Beyond Average Effects: The Uneven Promise of Child Marriage Bans

Preliminary Version[*]

October 24, 2026

Abstract

Child marriage remains widespread, although most countries set a legal minimum age of 18. Previous studies find that reforms rarely delay marriage on average, but evidence on how effects vary across contexts and on women's life-cycle outcomes remains limited. Combining WORLD policy data with Demographic and Health Surveys from 20 countries (1995 to 2023), I study child marriage bans (CMBs), reforms setting 18 as the minimum age without parental-consent exceptions, using a fuzzy regression discontinuity design based on birth-month eligibility across the largest dataset to date. While CMBs do not reduce child marriage on average, they do so where prevalence was already low, with weaker evidence of similar effects where informal unions were less common, the previous legal age was close to 18, and among girls aged 16 and 17. Independent of marriage timing, CMBs lead women to marry more educated husbands and reduce the justification of intimate partner violence. This suggests that CMBs reinforce pre-existing social shifts but cannot independently alter established marital institutions.

Keywords: Child marriage; child marriage bans; regression discontinuity design; heterogeneous treatment effects; women's life-cycle outcomes; intimate partner violence

1 Introduction

Child marriage remains widespread despite the global commitment to eliminating it by 2030 (UN General Assembly, 2015). Approximately 12 million girls younger than 18 years marry globally each year, corresponding to one girl every three seconds (UNFPA, 2026).[1] Beyond constituting a human rights violation (UN General Assembly, 2019), child marriage is a disruptive economic and social institution, capable of fundamentally reshaping girls' life trajectories. Marrying before adulthood is associated with lower educational attainment (Sunder, 2019), earlier and higher fertility (Wodon et al., 2016; Onagoruwa and Wodon, 2018), an elevated risk of experiencing intimate partner violence (IPV) (Kidman, 2016; Omidakhsh and Heymann, 2020), and reduced labour-force participation (Wilson, 2022). These consequences make child marriage more than a demographic outcome: it is an important constraint on women's human-capital accumulation and economic opportunities, with implications extending to households and societies more broadly.

In an effort to protect minors from these consequences, governments have increasingly adopted child marriage bans (hereafter CMBs). I define CMBs as legislative reforms that establish 18 years as the minimum legal age of marriage for women, irrespective of parental consent. By 2023, two thirds of countries had implemented a CMB (WORLD Policy Analysis Center (WORLD) (2023)). In spite of this, as of 2025, still one in five women aged 20 to 24 worldwide was married before the age of 18 (UNICEF, 2025), and recent evidence shows that CMBs frequently fail to bind (Collin and Talbot, 2023; Batyra and Pesando, 2021). While the adverse effects of child marriage are well documented, existing evidence on CMBs remains limited, mostly estimating average effects and examining only a few potential sources of heterogeneity (Wilson, 2022; Collin and Talbot, 2023). Such averages can conceal substantial variation, and consequently, it remains largely unknown under which conditions CMBs induce behavioural change and whether they reshape women's lives even where marriage is not delayed.

In this paper, I show that while CMBs do not reduce child marriage on average, they can do so where it was already less common, and that they reshape marriage markets and attitudes towards IPV even where marriage is not delayed. I combine the most recent WORLD Policy Analysis Center (WORLD) (2023) policy dataset, extended with enactment months, with all available waves of the Demographic and Health Surveys (DHS) for 20 countries that implemented a CMB between 1995 and 2023, and use a regression discontinuity design (RDD) around reform-specific birth-month cutoffs.[2] In countries with a low pre-reform child marriage rate, CMB eligibility reduces the probability of marrying as a minor by 6.8 percentage points, or about 39%, and even in the full pooled sample where the average effect is null, it increases husbands' educational

[1] I define child marriage as a formal marriage or informal union resulting in cohabitation. I do not distinguish between the two due to data limitations (see Section 3). Although child marriage affects both boys and girls, this paper focuses on girls and women, who are six times more likely to marry before adulthood and disproportionately bear its adverse effects (UNFPA, 2026).

[2] I employ the robust bias-corrected local-polynomial framework of Calonico et al. (2014). Eligibility depends on a woman's birth month relative to the reform date, a running variable individuals are unlikely to manipulate, so that comparing women born just before and just after the cutoff isolates the policy effect from regional and cohort trends. I correct for multiple hypothesis testing across the many subsamples and outcomes I consider.

attainment and reduces women's justification of IPV. This study contributes to the literature by assembling the largest cross-country dataset on CMBs to date, evaluating them with one consistent definition and design, documenting heterogeneity along previously unstudied margins, and analysing a broad set of life-cycle outcomes. Taken together, my results suggest that CMBs do not by themselves overturn established marriage practices but can reinforce social change that is already underway, which speaks to a central debate in development and gender economics on when legal reforms generate behavioural change.

Three main reasons explain why legal prohibitions often fail to prevent child marriage, and why their effectiveness reasonably depends on the local context. First, laws are often inconsistently enforced, with Collin and Talbot (2023) detecting enforcement in only around 10% of countries. I therefore consider both the effectiveness of the government as well as proxies of the social acceptance of child marriage as evidence indicates that laws are less likely to influence behaviour when they are in conflict with the prevailing norm (Acemoglu and Jackson, 2017).[3] Second, legal prohibitions can shift marriages involving minors from formal into informal or customary unions, as recorded Bellés-Obrero and Lombardi (2023) for Mexico and by Melnikas et al. (2021) for Malawi. I thus also consider the share of informal unions as a potential moderator of CMB effectiveness, as when they are more common, a substitution effect from formal to informal is more likely. Third, many legal frameworks contain exceptions, most prominently allowing marriage below 18 with parental consent (Arthur et al., 2018).[4] Because parents are commonly involved in arranging child marriages, such provisions significantly undermine the effectiveness of a legal minimum age. This is precisely why my definition of a CMB excludes reforms that retain a parental-consent exception. Importantly, weak enforcement does not imply that CMBs cannot change behaviour, as laws can act as signals of societal values that may shift customary practice (McAdams, 2000; Bénabou and Tirole, 2026).

My analysis reveals four main findings. *First*, CMBs do not reduce child marriage on average. This null result is robust to alternative bandwidths, functional forms and a coarser annual running variable, and is consistent with existing evidence (Collin and Talbot, 2023; Batyra and Pesando, 2021). *Second*, this average masks relevant heterogeneity in where CMBs bind. In countries with a low pre-reform child marriage rate, eligibility reduces child marriage by about two fifths relative to the control group, an effect that survives correction for multiple testing but is driven disproportionately by one country and depends on monthly identification. I find smaller, suggestive reductions in countries where informal unions are less common, where the previous legal minimum age was already close to 18, and in predominantly Muslim countries, while the effect is reversed where informal unions are more common. This pattern is consistent with CMBs binding only where informal unions cannot easily substitute for formal ones (Bellés-Obrero and Lombardi, 2023). In contrast to Wilson (2022) and Collin and Talbot (2023), I find no robust

[3] I consider the baseline prevalence of child marriage and the previous legal age.

[4] Other exceptions include the girl being pregnant or having given birth, religious or customary laws, and the approval of a court or similar entity (Arthur et al., 2018).

heterogeneity by urban residence or education, possibly reflecting differences in sample size and identification strategy.

Third, CMBs may delay marriage among women just below the new legal age. While the effect at 18 is null on average, I find suggestive reductions of about 6 to 10% in the share of women married at ages 16 and 17, relative to the control group, in an extended 24-country sample.[5] This is in line with Wilson (2022), who finds a positive effect on continuous age at marriage despite a null effect on marrying before 18.

Fourth, CMBs shape marriage markets and attitudes even when they do not delay marriage. Eligibility lowers the justification of IPV by about a tenth, and by about a fifth in countries with a low child marriage rate. Further, CMBs shift women's husbands towards secondary and higher education. These effects appear even in the full pooled sample and in subsamples where the effect on marital timing is null, which suggests that legal reform can operate through channels other than solely delayed marriage itself, for instance, by shifting social norms on IPV or by altering which unions form and are formalised. In contrast, I find no effects on women's own education, fertility, employment, bargaining power, or reported experience of IPV.

This paper contributes to the existing literature in four ways. *First*, I construct what is, to the best of my knowledge, the largest cross-country dataset assembled to study the consequences of CMB legislation without parental-consent exception. Sample sizes of previous papers range from single-country case studies (e.g., Bellés-Obrero and Lombardi, 2023, for Mexico; McGavock, 2021, for Ethiopia) to a maximum of 17 countries (Le et al., 2025; Wilson, 2022). My sample extends this to 20 countries by using the latest WORLD Policy Analysis Center (WORLD) (2023) release, which existing evaluations do not yet incorporate. This provides the statistical power and institutional variation needed for my heterogeneity analysis. To analyse the effects on girls aged 16 and 17, I additionally construct an extended sample of 24 countries by relaxing the restriction to age 18 used elsewhere in the paper.

Second, I provide a unified causal evaluation applying a consistent CMB definition and econometric approach throughout. Existing quasi-experimental studies vary in how they define a CMB, most prominently in whether they account for parental-consent exceptions. That this matters is highlighted by Kim et al. (2013) who find that CMBs without such exceptions significantly reduce adolescent fertility while those retaining them are indistinguishable from having no legal minimum age at all. Existing studies also alternate between difference-in-differences and RDDs with considerable variation in bandwidth, clustering and polynomial choice, limiting comparison and generalisability.[6] I apply a single CMB definition, excluding reforms with parental-consent exceptions, and identify causal effects by employing a robust bias-corrected RDD following Calonico et al. (2014) around reform-specific age cutoffs, pooling reform-eligibility variation across the full sample. Month-level reform and birth records further improve identification

[5]The extended sample adds countries with sufficient data at these younger ages. These effects are only marginally significant in the main sample. Placebo cutoffs show no significant effects.

[6]Table A1 gives an overview of the most relevant studies for this paper.

around the cutoffs relative to the annual eligibility measures standard in the literature.[7]

Third, I provide the most comprehensive evidence to date on treatment heterogeneity. Treating average effects as representative risks masking exactly the variation that determines when legislation binds and while existing studies estimate small or null average effects across or within countries, evidence on treatment heterogeneity is recent and limited to a narrow set of margins. I both test whether existing evidence on treatment heterogeneity holds in this paper's larger sample, and provide novel evidence on previously not considered dimensions, including the baseline prevalence of child marriage, and informal unions, as well as regime type or rural population share.

Fourth, I test whether CMBs reshape women's life-cycle and marriage market outcomes, even where they fail to delay marriage itself. Existing evidence on downstream effects is fragmented across studies with a single or only a few outcomes, including early childbearing (Kidman et al., 2024; Kim et al., 2013; Maswikwa et al., 2015; Rokicki, 2021), attitudes toward IPV (Omidakhsh and Heymann, 2020), educational attainment and employment (Wilson, 2022), and infant mortality (Le et al., 2025). I instead consider a comprehensive set of outcomes, spanning fertility, education, employment, IPV, household decision-making, and marriage-market outcomes within one unified framework. To do so, I rely primarily on ITT effects via reduced-form estimates, interpreting fuzzy local average treatment effects (LATE) only where the first stage is sufficiently strong. Thereby, I detect effects even where CMB eligibility does not reduce child marriage.

Beyond the child marriage literature, this paper relates to two broader literatures. First, it speaks to research on how laws shape behaviour and norms (Acemoglu and Jackson, 2017; McAdams, 2000; Bénabou and Tirole, 2026). Second, it relates to the economics of marriage markets, where marriage timing affects premarital investments, matching and bargaining within the household (Bergstrom and Bagnoli, 1993; Chiappori et al., 2009, 2017), and where marriage payments and household constraints drive early marriage (Corno et al., 2020; Corno and Voena, 2023). By showing that CMB eligibility shifts women's husbands towards higher education and lowers the justification of IPV even where marital timing does not change, my results suggest that minimum-age laws can reshape partner selection and household norms through channels beyond delayed marriage.

The remainder of this paper is organised as follows. Section 2 provides an overview of the institutional setting and conceptual framework. Section 3 describes the data employed in this analysis. In Section 4, I outline the empirical strategy, Section 5 presents and discusses the results, Section 5.3 presents robustness checks, and Section 6 concludes.

[7] Only Batyra and Pesando (2021) similarly employ monthly timing in an RDD context. Collin and Talbot (2023) rely on a coarser annual measure due to reporting heaping. I use monthly data in my baseline specification and test for digit preference by country. Birth months show heaping in nine countries, most plausibly due to recall and imputation, and excluding them does not strengthen the first stage. I also report results using an annual running variable (seef Section 5.3).

2 Background

2.1 Institutional Setting

According to the *Convention on the Rights of the Child*, a child is any human being under the age of 18 years (United Nations, 1989). Hence, in this paper, child marriage refers to any marriage or similar union, such as informal or customary, entered into by a person under 18 years of age. In 1995, governments articulated a global commitment to eradicate child marriage in the *Beijing Declaration and Platform for Action* (UN Women, 1995). The declaration explicitly targets forced and underage marriage by calling on governments to take legislative action.[8] Since then, many countries have enacted legislation aimed at protecting minors from child marriage. By 2023, 92% of countries had set 18 as the legal minimum age of marriage, or 67% once parental-consent exceptions are taken into account, the latter representing an increase of 19 percentage points compared to 2013 (WORLD, 2013). Globally, between 1999 and 2024, the share of women aged 20 to 24 who married before 18 declined by 6 percentage points, from 25% to 19%, while the share who married before age 15 fell by half, from 8% to 4% (UNICEF, 2025). Despite this progress, child marriage remains prevalent in many regions globally, for instance, 31% in Sub-Saharan Africa and 6% in Central Asia (UNICEF, 2025).

The potential consequences of not abiding by CMBs vary by country. While some countries solely set a minimum age without explicitly criminalising it, others enforce clear measures for perpetrators, including annulment of the marriage, warnings, fines, and imprisonment (UNFPA and UNICEF, 2020). According to international standards, no minor should face any form of punishment, but parents, guardians, officials, or other adults involved in the child's marriage (UNFPA and UNICEF, 2020). For instance, in Benin any responsible adult relative may face both prison sentences of several years as well as a fine, and between 2019 and 2023, of 3,310 registered child marriages 3,063 received some form of intervention (CGRA, 2025).[9] Nonetheless, even though the minor bride does not face legal consequences, both refusing the marriage as well as reporting it may have socio-economic consequences for her, due to family rejection, social exclusion, stigma, or the mental distress of having caused legal action against family members.

Similarly to potential consequences, the social norms around child marriage also differ across contexts. Although studies show that child marriage is more common when parents and communities support it, internalised norms do not necessarily equal social pressure to marry before adulthood (Psaki et al., 2021). For example, Steinhaus et al. (2019) find that while in a region with a high rate of child marriage in Malawi the empirical expectation for women in their community to marry before age 18 is very high (89%), the normative expectation to do so is significantly lower (53%). Taken together, the continued prevalence of child marriage paired with the variation in enforcement and socio-economic contexts underscores the need to

[8] Paragraph 274e: "Enact and strictly enforce laws to ensure that marriage is only entered into with the free and full consent of the intending spouses; in addition, enact and strictly enforce laws concerning [. . .] the minimum age for marriage and raise the minimum age for marriage where necessary" (UN Women, 1995)

[9] The form of intervention was not defined. Since the passing of the CMB in 2004, different laws have defined different fine amounts and imprisonment lengths.

understand when CMBs effectively delay marriage to adulthood, a global goal re-emphasised by Sustainable Development Goal (SDG) target 5.3, which seeks to eliminate child marriage by 2030 (UN General Assembly, 2015).

2.2 Conceptual framework

The diffusion of CMBs has been driven largely by international norms and commitments such as the United Nations Committee on the Rights of the Child (CRC) and the Committee on the Elimination of Discrimination against Women (CEDAW), so that CMBs have also been adopted where marriage below 18 years of age remained a common practice (Kim et al., 2013; Ebetürk, 2021). Economically, CMBs regulate a decision that is typically taken by parents but whose consequences fall largely on daughters. In particular in low-income households and regions where a bride price is customary, an early marriage can provide parents with a marriage payment, reduce the number of household members to support, and serve as informal insurance against income shocks (Corno et al., 2020; Corno and Voena, 2023). At the same time, early marriage frequently ends girls' schooling and thus reduces their human capital (Becker, 1964; Field and Ambrus, 2008), a cost borne mainly by the daughter herself. Since a minor cannot credibly commit to compensating her parents later for the costs of postponing her marriage, even altruistic parents might choose a marriage timing that is earlier than would be optimal for the family as a whole (Bergstrom, 1989; Baland and Robinson, 2000).

Child marriage can also persist as a coordination failure. In contexts where age at marriage signals a bride's quality, communities may remain in an early-marriage equilibrium even if all families would prefer and benefit from a delay, since no single family can deviate on its own without incurring a cost (Wahhaj, 2018; Buchmann et al., 2023). As a CMB applies to all families at once, it can in principle shift such an equilibrium. Crucially, weak formal enforcement therefore does not imply that no effect is to be expected. Laws can act as focal points and signals of societal values (McAdams, 2000; Bénabou and Tirole, 2026) through which they can potentially shift customary practice even if the CMB is implemented inconsistently (Aldashev et al., 2012). Beyond the forces of law and order, enforcement itself also relies on private reporting and is thus shaped by local norms (Acemoglu and Jackson, 2017).

The conditions under which CMBs bind, described in Section 1, can be tested in several dimensions. CMBs should be less binding where enforcement capacity is weak, where child marriage is common, and where informal and customary unions are widespread, as families can substitute formal marriage by informal ones (Melnikas et al., 2021; Bellés-Obrero and Lombardi, 2023). The effects may also differ with the rural and religious composition of a country, as location has been shown to shape enforcement (Wilson, 2022) and religion can influence attitudes towards family planning and consequently shape family behaviour (Heaton, 2011; Westoff and Bietsch, 2015). By raising the expected age at marriage, CMBs may, moreover, affect premarital investments and matching, and thus whom women marry (Bergstrom and Bagnoli, 1993; Chiappori et al., 2009).

However, the welfare effects of CMBs are ambiguous. As early marriage can be a rational response to missing credit and insurance markets and limited alternatives (Corno and Voena, 2023), a ban that removes this option without an adequate alternative may leave households worse off, as documented for the case of child labour bans (Bharadwaj et al., 2020), while it is more likely to raise women's welfare where viable alternatives exist, such as schooling and employment (Jensen, 2012; Baird et al., 2011; Bandiera et al., 2020). In addition, governments have also justified exceptions to a minimum marriage age with cases of elopement and premarital pregnancy, an argument that has been contested (Asadullah and Wahhaj, 2016). Importantly, this paper does not estimate welfare effects, which depend on individual circumstances the data do not capture, but evaluates whether and where CMBs change marriage behaviour and a broad set of welfare-relevant outcomes.

3 Data

3.1 Data Sources & Sample

To identify countries with a CMB, I use data at the country-level of WORLD (2023). As exceptions for parental consent effectively legalise marriage below the stated minimum age (see Section 1, I define a CMB as a legislative change establishing a minimum legal age of marriage for women 18 years or older, irrespective of parental consent. WORLD (2023) tracks whether marriage at a given age is legally permitted across all UN member states on an annual basis since 1995 based on primary legal sources. Furthermore, and crucial for this analysis, it distinguishes between legal marriage age with and without parental consent. Because identification is based on the age in months relative to CMB implementation, I extend the dataset by constructing a new variable that captures the month of enactment of each CMB within this sample. These enactment months are extracted from the original legislative sources.

As of 2023, 129 countries set the minimum legal age of marriage at 18 years or older (WORLD, 2023). To identify the year of CMB implementation, longitudinal data is required at the year level, as otherwise I can only assess whether there was a change between the three available datasets dating from 2023, 2019, and 2013, without the possibility of assessing changes prior to 2013. This data is available for 114 countries, predominantly located in the Global South.[10] Within this subset, 53 countries implemented a CMB between 1995 and 2023, of which 45 are featured in the DHS.[11]

The source of the individual and household-level data used in this empirical analysis stems from the women's questionnaire of the DHS, which provides nationally representative survey data for 91 countries on a wide array of socio-demographic variables, including education, family

[10]This subset of countries excludes almost universally high-income countries, small states and microstates, similar to the DHS, with 95.6% of DHS countries included in the WORLD longitudinal subset.

[11]Following verification of CMB years using WORLD (2023) and supplementary legislation, Peru and Nigeria were excluded. Peru's cited CMB year could not be confirmed. Ley Nº 31945 instead set a CMB in November 2023, too recent for this analysis. Nigeria's 2003 national CMB is not adopted by nine states and coexists with parallel Sharia legal systems (Fang et al., 2024), preventing clear identification of eligible individuals.

planning, IPV, and domestic violence attitudes (ICF, 2025).[12]

As the DHS data includes responses from women aged between 15 and 49, I restrict the sample to those aged 18 and above at the time of interview, since for younger respondents it cannot yet be known whether they will marry before turning 18.[13] Subsequently, I restrict the sample to countries with at least 36 months of birth-cohort coverage on each side of the cutoff, defined as the birth month of women who turned 18 in the month the CMB was implemented.[14] This removes countries where no DHS survey was conducted post CMB implementation, yielding a final sample of 20 countries.

Table 1 provides an overview of the countries included in the analysis with their respective CMB implementation date, the cutoff birth cohort, the DHS rounds employed, and their share of the full sample. In addition to the 20 countries included in the main sample, it also includes four additional countries that meet the data coverage requirements when considering the effects on women aged 17 and younger. The cutoff cohort corresponds to individuals who turned 18 in the month of CMB enactment, thereby generating a discontinuity in eligibility for legal protection under the reform.[15]

The majority of countries in the main sample are located in Sub-Saharan Africa (14), with the remainder in West Asia and North Africa (2), South Asia (2), Central Asia (1) and Europe (1). Because Sub-Saharan Africa is also the region where child marriage remains most common (UNICEF, 2025), the prevalence of child marriage in this sample is higher than the global average. Figure 1 depicts, by birth year, the share of women in the sample married before age 18 and before age 15, both declining steadily across cohorts, from around 50% to 30% and from 12% to 7% respectively. Figure 2 complements this by comparing marriage timing directly between women eligible and ineligible for protection under a CMB, restricting the sample to those born within three years of their country's cutoff so the two groups are drawn from comparably-aged cohorts. Eligible women are consistently less likely to be married at any given age than ineligible women, with the gap opening early and persisting through age 35.

3.2 Child Marriage & Life-Cycle Outcomes

Marital Timing. To measure marital timing, I rely on the self-reported age at first marriage or cohabitation. As DHS data only distinguishes between formal and informal for the current union, not for the first one, this variable captures union formation more broadly, including civil, religious, and customary unions, as well as informal cohabitation. Although this more accurately

[12] Where available, I use consistently coded datasets from the Integrated Public Use Microdata Series (IPUMS) (Boyle et al., 2024). The remaining datasets were downloaded and integrated manually.

[13] Without this restriction, respondents aged 15 to 17 could only be coded zero (if already married) or missing (if not, since it is not yet known whether they will marry before 18), never one, mechanically inflating the measured child-marriage rate and biasing cohort comparisons, since eligibility is itself defined by birth cohort.

[14] The threshold corresponds to the median of the country-level MSE-optimal bandwidths for the effect on marital timing, so that each included country has enough data to support its own optimal estimation window, rather than merely a nominal presence on both sides of the cutoff. This affects four countries.

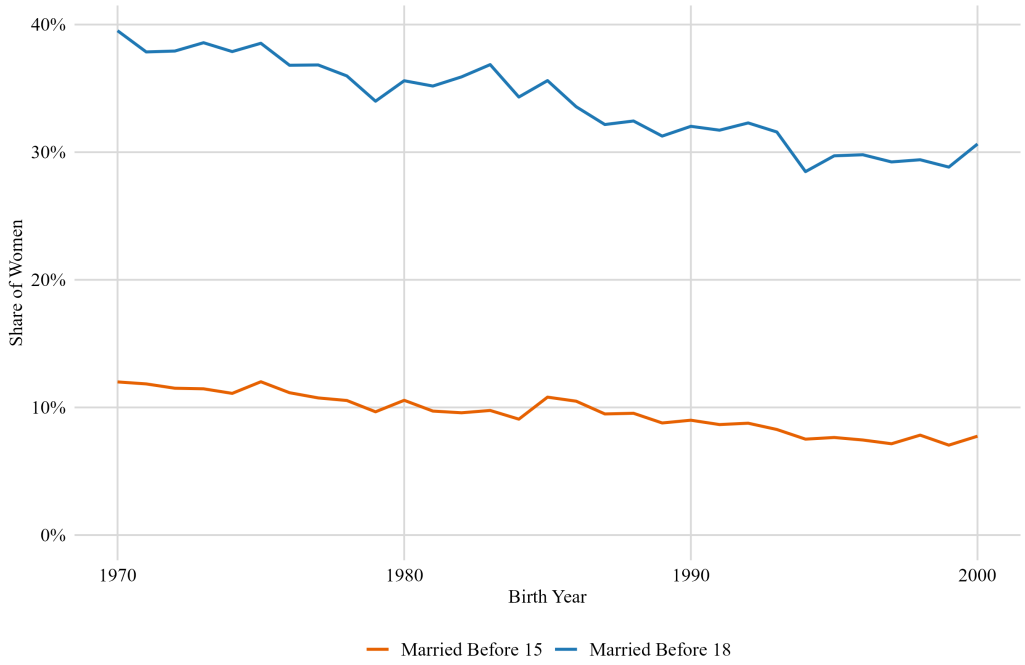

[15] I define eligibility using age 18 rather than the pre-reform legal minimum, since several countries lacked a clearly defined minimum age prior to reform, and separately examine heterogeneity by the pre-reform minimum age.

Table 1: Sample Countries and CMB Implementation Dates

	Child Marriage Ban		DHS Survey Rounds		
Country	CMB Date	Cutoff Cohort	Oldest	Newest	% of Sample

Notes: † featured in the extended sample only. CMB date refers to the date on which the minimum legal age of marriage for women irrespective of parental consent was increased to a minimum of 18 years. The cutoff cohort refers to the birth month of women who turned 18 in the month the CMB was implemented, the first cohort eligible for protection under the CMB. % of Sample is calculated over the 20 countries in the main sample only, and is therefore left blank for the four countries featured in the extended sample only.

Figure 1: Share of Women Married Before Age 18 and 15, by Birth Year

Notes: Share of women married before age 18 (blue) and before age 15 (orange), by birth year from 1970 to 2000, in the full sample (20 countries, 615,771 women). Solid lines are weighted, dashed unweighted.

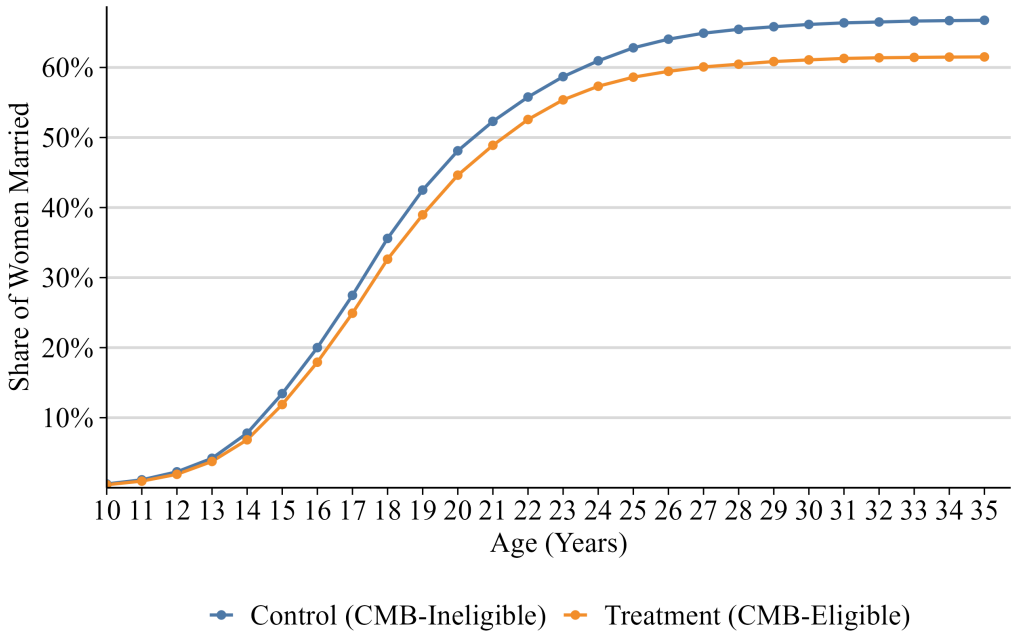

captures the reality of child marriage, it does potentially mask a substitution effect from formal to informal marriage.[16] Consequently, my main outcome is a binary indicator equal to one if a woman first married or cohabited at or after age 18, or has never married, and zero otherwise, so that a positive estimate indicates a reduction in child marriage. I use this binary indicator rather than continuous age at first marriage, since the latter is only defined for women who are currently or were formerly married and would exclude women not yet married at the time of interview. I test robustness using age at first marriage as the outcome instead (see Section 5.3). To further assess differences by marital status, I restrict the sample to ever-married women and the exclude marriages potentially driven by pregnancy. As both are themselves potentially affected by the reform, I do not treat them as a heterogeneity in the main results, but instead report them as robustness checks in Section 5.3.

Life-Cycle Outcomes. To assess the effect of CMBs on women's life-cycle outcomes, I consider the following variables, categorised into four panels.[17] Each life-cycle outcome is assessed as the ITT effect of CMB eligibility and, only in subsamples with a first-stage F-statistic of at least 10, additionally as the LATE for compliers, women whose marriage timing responds to eligibility (see Section 4). While existing evidence points to adverse average effects of child marriage on each of these outcomes, less is known about the effects of CMBs themselves, as discussed below.

[16] Among women currently in a union, 88.7% are married and 11.3% are cohabiting.

[17] See Table A2 for the respective DHS variable code, and descriptive statistics for the full sample and by treatment status.

Figure 2: Cumulative Share of Women Married, by Age and Eligibility

Notes: Weighted cumulative share of women married by each age, separately for the CMB-eligible (treatment) and CMB-ineligible (control) groups, restricted to a three-year bandwidth around each country's eligibility cutoff so the two groups are drawn from comparably-aged birth cohorts.

Panel A: Fertility. Child marriage is associated with earlier childbearing (Wodon et al., 2016) and higher completed fertility (Onagoruwa and Wodon, 2018). As CMBs seek to reduce child marriage, they should mechanically delay the onset of fertility. For completed fertility, this mechanism is less direct, as even if the first birth occurs later, women could compensate by having children in closer succession thereafter. To test whether CMBs affect fertility, I consider two outcomes. First, *Total Fertility*, measured as the total number of children the respondent has given birth to as of the time of the survey, including children who have since died. Second, a binary indicator, *Birth After 18*, equal to one if the respondent's first birth occurred at or after age 18, so that a positive coefficient corresponds to a lower incidence of adolescent childbearing.

Panel B: Education and Employment. Research shows that child marriage is associated with lower educational attainment (Sunder, 2019) and reduced labour-market participation (Wilson, 2022). Early marriage may negatively affect schooling by imposing domestic responsibilities before girls complete their education. Consequently, CMBs should, by delaying marriage, raise educational attainment. However, this mechanism presumes that marriage timing itself drives the schooling decision, while it might also be the case that girls who never attended school or dropped out at an early age are more likely to marry early regardless of the legal minimum age, in which case CMBs would have no effect on educational attainment. Because women are already above primary-school age at the age-18 cutoff, I only assess effects on completing secondary education (*Secondary Education*), where remaining in school rather than marrying is the plausible margin. The reverse-causality concern above applies to it as well. Similarly, child marriage may constrain a woman's ability to engage in paid work, both directly through domestic

responsibilities and indirectly through the education channel above, as reduced human-capital accumulation lowers the returns to, and likelihood of, labour-market participation (Becker, 1964). However, using an instrumental-variable strategy in India, Dhamija and Roychowdhury (2020) find that while delayed marriage raises education, it does not significantly affect labour market outcomes, attributing this null result to a backlash effect, whereby older brides face greater resistance from their husbands that offsets the labour-market gains otherwise expected from more schooling. I measure this outcome using a binary indicator, *Worked Last Year*, equal to one if the respondent engaged in any paid work outside the household in the past year.

Panel C: Decision-Making & IPV. Evidence suggests that child marriage reduces women's intra-household bargaining power and increases their risk of experiencing IPV. Tauseef and Sufian (2024) find that women who marry later have higher empowerment scores, while Kidman (2016) show that women who marry as children face an increased risk of experiencing IPV, with significant variation across countries. If a later age at marriage increases a woman's relative bargaining power within the household, CMBs should, by delaying marriage, reduce exposure to and acceptance of IPV. *Decision-Making* captures who usually makes household decisions, such as purchases or the respondent's own health care, across seven questions. Each response is assigned one point if the respondent decides alone, 0.5 if jointly, and zero if she is not involved, and the index is the average across all available answers. IPV attitudes are captured via *IPV Justification*, an index on whether the respondent considers it justified for a man to beat his wife or partner in specific circumstances, such as arguing or burning food. The indicator captures the fraction of yes answers, ranging from 0 to 1. A higher value means greater justification of IPV. The variables that capture the personal experience of IPV stem from an optional module that is not available for all countries or survey rounds, resulting in a smaller sample size for these outcomes of approximately 22% of the full sample. The module contains eleven questions asking whether the respondent has experienced different forms of IPV, including emotional, physical, and sexual abuse. *IPV Experience* is a binary indicator equal to one if the respondent reports any of the eleven forms and zero otherwise. To assess differential effects on different dimensions of IPV, I further include binary indicators equal to one if she reports any emotional, physical or sexual IPV (*IPV Experience: Emotional*, *IPV Experience: Physical* and *IPV Experience: Sexual*).

Panel D: Marriage Market Outcomes. Evidence on how child marriage shapes partner selection is more limited than for the other panels considered here. Standard marriage-market reasoning suggests that women who marry later have greater agency in partner selection (Becker, 1973), so CMBs may affect not only the timing of marriage but also whom a woman marries through positive assortative matching (Chiappori et al., 2017), predicting better-educated husbands and a narrower spousal age gap.[18] However, using a reform-based design in Bangladesh, Tauseef and Sufian (2024) find that delayed marriage raises bargaining power without producing

[18]Husband characteristics refer to different-sex couples only, reflecting the DHS survey design, which collects spousal information exclusively within the context of heterosexual marriage.

observably higher-quality spouses, suggesting the two need not move together, making this panel a complement to the previous panel. Husband characteristics are only observed for currently married women and reflect their current rather than necessarily their first husband. If CMBs mainly reduce the probability of marrying rather than change partner selection, this comparison is drawn on an endogenously selected subsample, so estimates here reflect sorting among women who remain married, not unconditional effects of the reform. Reassuringly, CMB eligibility does not predict the likelihood of being married by age 30 (coefficient ≈ 0, $p = 0.998$), suggesting no differential selection into the currently-married sample used for this panel. Accordingly, I assess whether eligible women marry more educated husbands, using a continuous variable ranging from 0 (no education) to 3 (higher education), *Husband Education*. In the appendix, I additionally report a dummy for each education level to show where the shift occurs. Whether CMB eligibility's effect on husbands' education is a favourable outcome for the wife is itself unclear, and existing evidence is divided on this. From a bargaining perspective, relative spousal education, a wife's education relative to her husband's, rather than either spouse's absolute level, is commonly used as a proxy for her intra-household bargaining power, so a widening gap in the husband's favour could plausibly signal reduced rather than improved standing for the wife (Frempong and Stadelmann, 2024). Conversely, more educated husbands are sometimes found to be less likely to justify or perpetrate IPV, consistent with a protective, more gender-equitable effect of male education, though this relationship is inconsistent across countries and can even reverse (Tsala Dimbuene et al., 2024), a status-threat pattern running in the opposite direction. Given this ambiguity, I do not take a stance on which mechanism dominates and instead let the data speak to the direction of the effect. Further, evidence suggests that women who marry before adulthood tend to marry significantly older men (Dommaraju, 2024; Pru et al., 2024). I therefore construct a binary indicator for an age gap of at least five years between the respondent and her current husband (*Age gap* $\geq$ *5 years*).[19]

3.3 Heterogeneity Analysis

This subsection describes the individual- and country-level characteristics used to examine heterogeneity in CMB effects.[20] These subsamples test whether CMB effectiveness and downstream life-cycle outcomes vary systematically with individual characteristics and the institutional environment. To avoid conditioning on outcomes of the reform, I restrict individual-level heterogeneity to characteristics that are fixed, or very likely to be fixed, before age 18. Country-level variables refer to the year of CMB implementation or to the weighted average of the five birth cohorts preceding the reform, unless otherwise indicated. To account for the large number of subsamples, 26 in total, Benjamini-Hochberg (BH) adjusted p-values are reported for all samples (see Section 4).

[19] Because the DHS reports information only on the current husband, this may bias the age-gap results downward, since women who married significantly older men may since have been widowed or remarried a younger husband.

[20] See Table A2 and Table A3 for descriptive statistics of the individual- and country-level variables for the full sample and by treatment status.

Individual-Level Heterogeneity. Wilson (2022) shows that location matters for CMB enforcement. Using this paper's larger sample and unified estimation strategy, I test whether this finding holds by distinguishing between women living in rural and urban areas (*Rural vs. Urban*). Further, I split the sample by whether the respondent identifies as *Christian* or *Muslim*, the two prominent religions in the sample as research shows that religion can shape fertility and family-planning behaviour (Heaton, 2011; Westoff and Bietsch, 2015). Both variables are recorded at the time of survey, and even though religious affiliation is typically fixed in childhood, I cannot exclude that women moved residence or converted to a different religion since. I therefore complement both splits with a country-level measure on the respective populations share below. Further, both variables are included as control variables (see Section 4.

To assess whether CMB impacts vary by age, I stratify the sample into three roughly equally sized groups by age at survey: *Age 18–24*, *Age 25–34* and *Age 35+*. This allows me to assess separately the short-, medium- and long-term consequences of delayed marriage. A potential concern is that this stratification reflects differences in which countries implemented their CMB when, rather than genuine variation by age. This is not the case, however, since I pool all available DHS survey rounds, and each age subsample includes all 20 sample countries.

Osili and Long (2008) shows that higher education is associated with later marriage, while Ahonsi et al. (2019) find that girls who never attended school are more likely to marry as children than those who ever attended. Unfortunately, I do not observe the education level at the time of first marriage. Given the reverse causality underlying the relationship, I only consider primary education, as it is credibly pre-determined. Only 1.04% of women in the sample married before age 12, a common benchmark for primary school completion.[21] Accordingly, I distinguish between women without and with completed primary education (*No Primary Education* / *Primary Education*).

Country-Level Heterogeneity. Legislation does not immediately change the underlying socio-economic context, so a CMB may bind less where child marriage is common (see Section 2). As the baseline prevalence of child marriage captures the extent to which a CMB departs from the prevailing marriage norm, understanding how it affects policy effectiveness is crucial to anticipate when a CMB can have the intended protective effect. I thus hypothesise that CMBs have a smaller effect in countries with a higher pre-reform child marriage rate, as the perceived risk of non-compliance may be lower where the practice is relatively widespread.

I classify countries into three groups based on the World Bank estimate of the share of women aged 20 to 24 who were married before 18, for the year closest to the reform: 0-20% (*Low Child Marriage Rate*), 20-40% (*Medium Child Marriage Rate*), and above 40% (*High Child Marriage Rate*). I use round percentage thresholds rather than sample-specific terciles, since several countries' rates cluster too tightly for a data-driven cutoff to be robust. Further, fixed thresholds are more easily interpretable and comparable across studies.

[21] By contrast, secondary school is typically completed around age 17 or 18, by which point 23.6% and 32.1% of women in the sample, respectively, had already married.

Besides the prevalence of child marriage at the time of CMB implementation, I use two other proxies to investigate differences by existing marital practice: The prevalence of informal unions and the previous legal age. To account for the potential substitution into informal unions discussed above, I classify countries by the prevalence of informal unions (*Low / High Informal Unions*). Besides making circumventing the protective effect of CMBs, a substitution towards informal unions also results in women losing the legal rights associated with marriage. As the DHS does not record the type of a woman's first union, I use the share of women currently in a union who report cohabiting rather than being married, measured among the same cohorts and split at the cross-country median. I further consider the extent of legislative change, as behaviour may differ when a narrow gap is closed as opposed to when a CMB is introduced where previously no legal age existed. Following Wilson (2022), I split the sample into three subsamples based on the previous legal age: *Previous Age 16/17*, *Previous Age 14/15* and *No Previous Age*. This allows me to assess whether the pattern observed by Wilson (2022) holds across my larger sample and unified estimation strategy.

To complement the individual-level distinction between women residing in urban or rural areas, I classify countries by the share of women living in rural areas (*Low / High Rural Share*), measured among the five birth cohorts preceding the reform, and split countries at the cross-country median of this share. Further, I classify countries as predominantly Christian or predominantly Muslim if more than half of women in these cohorts identify with the respective religion (*Predominantly Christian / Predominantly Muslim*).[22]

Besides socio-economic conditions, the effectiveness of policy implementation also depends on state capacity, institutional quality, and governance (Besley and Persson, 2009, 2010). To capture this, I consider the following stratifications. First, I categorise countries into *Autocracies*, *Anocracies*, and *Democracies* based on their Polity Project Polity Score (Marshall and Gurr, 2020). This score ranks regimes on a 21-point scale from hereditary monarchy to consolidated democracy. Second, as a proxy for a state's administrative and judicial capacity to enforce the CMB, I classify countries by the World Bank Government Effectiveness indicator (Kaufmann et al., 2011), which captures the quality of public service delivery, policy formulation, and implementation (*Low / High Government Effectiveness*).[23]

Strong First Stage Countries. Finally, I estimate the effect on marital timing separately for each country to construct a subsample of countries where the first stage is statistically significant at the 10% level, with controls, and positive, or in other words, countries in which CMBs successfully delayed marriage. As this selects countries on their own estimate, p-values in this category are conditional on the selection and it is not part of the BH family.

[22]This classifies 10 countries as predominantly Christian and 9 as predominantly Muslim. Nepal, where most women are Hindu, belongs to neither group.

[23]This stratification uses each country's value from the year closest to its own reform year, split at the cross-country median of that single-year measure.

4 Empirical Strategy

To estimate the causal effect of CMBs on marital timing and on women's life-cycle outcomes, I exploit the discontinuity in eligibility for protection under a CMB, comparing women who were just young enough to be protected by the reform with those who were just too old (Lee and Lemieux, 2010). Although governments can prohibit child marriage, they cannot perfectly ensure compliance, as informal and customary unions may still take place despite the prohibition of legal unions involving minors and the establishment of potential penalties (Collin and Talbot, 2023; Bellés-Obrero and Lombardi, 2023). Accordingly, I primarily estimate the effect of CMB eligibility on marital timing (1) and on life-cycle outcomes (2) as ITT effects, which correspond to the policy-relevant quantity.

Where eligibility significantly affects marital timing, I additionally use it as an instrument for marrying at 18 or later in a fuzzy RDD (3). This scales the ITT on life-cycle outcomes by the effect on marital timing and identifies the effect of delayed marriage for compliers, women near the cutoff who marry at 18 or later if eligible but before 18 otherwise. Although compliers are the women the CMB targets, they are a specific subpopulation, so the fuzzy estimate speaks only to them. I report fuzzy estimates only for subsamples with a strong first stage (F-statistic of at least 10) and never for the full sample, and I do not report an estimate where it is below 10.

$$\text{Married}_{ijt}^{18+} = \alpha_0 + \alpha_1 Z_i + \alpha_2(B_{ij} - c_j) + \alpha_3(B_{ij} - c_j)Z_i + \boldsymbol{\alpha}_4'\mathbf{X}_{ij} + \mu_j + \lambda_t + e_{ijt} \qquad (1)$$

Equation (1) estimates the effect of CMB eligibility on marital timing, where, following Batyra and Pesando (2021), $\text{Married}_{ijt}^{18+}$ is a binary indicator for the absence of child marriage. It equals one if individual i in country j, observed in DHS survey year t, reports that her first marriage or cohabitation occurred at or after age 18, or if she has never married, and zero if it occurred before age 18. The coefficient α_1 is the ITT effect of eligibility on this probability and is also the first stage of the fuzzy design introduced below. A positive coefficient thus indicates that eligibility delays marriage.

Eligibility is assigned by comparing the respondent's birth month to a country-specific cutoff, set so that eligible respondents had not yet turned 18 when the CMB took effect. Formally, $Z_i = \mathbb{1}[B_{ij} \geq c_j]$, where B_{ij} is the individual's month of birth and c_j is the country-specific cutoff birth month. The running variable is the month of birth centred relative to the country-specific cutoff, $B_{ij} - c_j$, so that the coefficient of interest, α_1, can be interpreted as the size of the discontinuity in the probability of marrying at 18 or later at the cutoff.[24]

The specification includes an interaction between the centred running variable and the eligibility indicator Z_i to allow for separate linear trends on either side of the threshold, as recommended by Cattaneo and Titiunik (2022). All specifications include country fixed effects, μ_j, and survey-year fixed effects, λ_t, which account for time-invariant institutional differences across

[24] As a robustness check, I additionally construct the running variable using year of birth rather than month, since birth month is more prone to recall error and heaping in DHS data. See Section 5.3.

countries and global survey-year shocks, respectively, and the main specification additionally includes the controls $\mathbf{X}_{ij}$ described below.

$$Y_{ijt} = \gamma_0 + \gamma_1 Z_i + \gamma_2(B_{ij} - c_j) + \gamma_3(B_{ij} - c_j)Z_i + \boldsymbol{\gamma}_4'\mathbf{X}_{ij} + \mu_j + \lambda_t + v_{ijt} \tag{2}$$

Equation (2) estimates the corresponding ITT effect on each life-cycle outcome Y_{ijt}, regressing it directly on the eligibility indicator Z_i and using the same running variable, interaction term and fixed effects as (1). The coefficient γ_1 captures the effect of being eligible for protection under a CMB regardless of whether the individual's own marriage timing responded to the reform. Because γ_1 requires neither monotonicity nor the exclusion restriction to be interpreted causally, it remains valid even where the effect on marital timing is weak, unlike the fuzzy estimate in (3).

$$Y_{ijt} = \beta_0 + \beta_1 \widehat{\text{Married}}_{ijt}^{18+} + \beta_2(B_{ij} - c_j) + \beta_3(B_{ij} - c_j)Z_i + \boldsymbol{\beta}_4'\mathbf{X}_{ij} + \mu_j + \lambda_t + u_{ijt} \tag{3}$$

Equation (3) is the fuzzy second stage, in which Y_{ijt} is regressed on the predicted probability of marrying at 18 or later, $\widehat{\text{Married}}_{ijt}^{18+}$, obtained from (1). β_1 identifies the LATE for compliers and equals the Wald ratio γ_1/α_1, as both are estimated jointly on a single bandwidth for the effect on marital timing and on the outcome.

Estimation. Equations (1) to (3) are estimated using the robust bias-correction procedure of Calonico et al. (2014), implemented through local linear regression within a data-driven mean squared error (MSE) optimal bandwidth on both sides of the cutoff.[25] I estimate each equation in two specifications. First, I only include country and survey-year fixed effects. Second, I add controls $\mathbf{X}_{ij}$ for rural residence and religion. As the DHS records current rather than childhood residence, rural residence is only partly pre-determined, but it shapes enforcement (Wilson, 2022). Religion enters through separate indicators for Christian and Muslim, as it can shape gender norms and attitudes towards family planning (Makate and Makate, 2018; Turner and Götmark, 2023), and it is usually determined in childhood.[26] Both variables are observed for 96.4% of respondents. The specification with controls is my main specification and uses only these women. I report the specification without controls, which uses all women and sets the terms $\boldsymbol{\alpha}_4'\mathbf{X}_{ij}$, $\boldsymbol{\gamma}_4'\mathbf{X}_{ij}$ and $\boldsymbol{\beta}_4'\mathbf{X}_{ij}$ to zero, alongside it throughout and in the appendix. Residence and religion are also used to split the sample in the heterogeneity analysis. As religion is missing for 3.6% of respondents, mostly in entire surveys from Egypt, Liberia, Mozambique, Kenya and Comoros, the specification that controls for rural residence and religion uses the remaining sample.

[25] This procedure selects the bandwidth that minimises the MSE of the local-linear estimate by balancing squared bias against variance. It then subtracts an estimate of the remaining curvature bias, obtained from a local quadratic regression on a separate pilot bandwidth, and computes standard errors that account for the additional uncertainty from estimating this bias, so that confidence intervals remain valid at the MSE-optimal bandwidth. Robustness to a CER-optimal bandwidth and a local quadratic specification is reported in Section 5.3.

[26] The baseline category comprises women with no religion and those affiliated with other religions, such as Judaism, Hinduism or traditional and spiritual beliefs.

Standard errors are clustered at the primary sampling unit level, the finest geographic unit available in the DHS. Survey weights are normalised within each country-survey cell so that every survey contributes equally to the pooled sample, regardless of its underlying size.[27] For each fuzzy estimate, I report the first-stage F-statistic at the fuzzy bandwidth. In the few cases where an estimate exceeds half a standard deviation of the outcome, I re-estimate it excluding country-survey cells observed on one side of the cutoff only and mark it in the tables.[28]

Although the marital timing outcome and most life-cycle outcomes are binary, I estimate them using local linear regression rather than a logit or probit model. Since the conditional probability is left unrestricted outside the local window, the linear approximation within the bandwidth imposes no global functional form (Lee and Lemieux, 2010). Given the large number of subsamples and outcomes considered throughout the results section, I additionally report BH adjusted p-values, which control the expected share of false positives among the rejected hypotheses. The correction is computed separately for each specification and outcome across the full sample and the 26 subsamples. The countries with a strong first stage and the sample restrictions used as robustness checks are not part of this family.

Identification Assumptions. Identification of the ITT effects in (1) and (2) rests on the following two assumptions.[29] First, individuals cannot manipulate their recorded birth month to change eligibility, so the density of the running variable is smooth through the cutoff. This fails if individuals are able to manipulate their recorded birth month and subsequently their eligibility status. While actual birth and marriage months are not manipulable, imputation of missing information as well as misreporting or recall bias in the self-reported DHS data remains possible. I test for this directly using the manipulation test of Cattaneo et al. (2020), run both on the pooled sample and separately for each country. The pooled test rejects continuity of the density at the cutoff and I detect heaping in nine countries after correcting for multiple testing, most plausibly driven by recall or imputation, but I cannot rule out more systematic misreporting. In Section 5.3, I show that excluding these countries does not strengthen the first stage and that the main results are largely, but not fully, robust to excluding observations close to the cutoff.

Second, since identification requires conditional expectations to be continuous at each country's own reform date, a confound coinciding with any single country's cutoff would bias that country's local estimate, and I assess how far any single country drives the pooled estimate with a leave-one-country-out analysis (Section 5.3). A confound biasing the pooled estimate systematically, rather than through one country, would additionally require coinciding independently with several countries' own idiosyncratic reform dates and affecting precisely the age cohort that was just eligible at each of them, which is unlikely given that these dates are staggered and unrelated to one another. I also check covariate balance at the cutoff as an indirect test.

[27] Robustness to instead scaling survey weights with each survey's own sample size is reported in Section 5.3.

[28] I report the re-estimated value where it is plausible. Estimates that remain implausible are marked as unstable and excluded from the multiple-testing correction.

[29] Detailed results for the respective tests can be found in Section 5.3.

Identification of the LATE in (3) additionally rests on the following three assumptions. First, the instrument must be relevant, resulting in a genuine discontinuous change in the probability of marrying at 18 or later, so that α_1 in (1) is not zero. I therefore report fuzzy estimates only where the effect on marital timing is significant and rely on the reduced form (2) elsewhere, including in the full sample.

Second, monotonicity requires that crossing the eligibility cutoff weakly increases the probability of marrying at 18 or later for every woman, so that no woman is induced to marry earlier by becoming legally eligible for protection (Hahn et al., 2001; Imbens and Lemieux, 2008). This is plausible given the direction of the legal change, since a binding minimum-age law raises the cost of marrying before 18 and cannot lower it.

Third, the exclusion restriction requires that eligibility affects outcomes only through marrying at 18 or later. This is a strong assumption, since eligibility may also operate through other channels, such as partner selection or attitudes towards IPV, and the ITT effects I find where marital timing is unaffected suggest it may not hold. I therefore interpret fuzzy estimates cautiously and treat the ITT as my primary estimates. Under these assumptions, the fuzzy RDD estimate identifies the LATE for compliers, the subset of women near the cutoff whose marriage timing responds to the reform, and not the average treatment effect for the full population.

5 Results

5.1 Child Marriage Bans and Early Marriage

This section examines the effect of CMB eligibility, defined by birth month relative to the reform date, on marital timing, measured by the probability of not marrying or cohabiting before age 18, so that a positive estimate indicates a reduction in child marriage. While the main results are presented in this section, detailed results can be found in Appendix Section D.1 and robustness checks in Section 5.3.

Full Sample. Table 2 reports the effect in the full pooled sample across five specifications. Column (1) includes neither fixed effects nor controls. Column (2) adds country and survey-year fixed effects, columns (3) and (4) additionally control for religion and for rural residence respectively, and column (5) includes both and is my main specification. Religion is not observed for 3.6% of women (24,991 of 687,055), who almost exclusively reside in Egypt, Liberia, Mozambique, Kenya and Comoros. To reflect differences by specification rather than sample, all five columns use the same sample of women with rural residence and religion observed. In every specification, CMB eligibility has no perceptible effect on child marriage, with coefficients ranging from 0.4 to 1.0 percentage points, all statistically indistinguishable from zero. The null also holds under alternative specifications, including an annual running variable, CER-optimal bandwidth, a local quadratic polynomial, and fixed bandwidths (see Section 5.3). In all cases coefficients are at most 1.5 percentage points, and none is significant at the 5% level.

Table 3 reports the full sample estimates both without and with controls, both including country and survey-year fixed effects. The first specification uses all observations, once controls

Table 2: Effect of CMB Eligibility on Marital Timing: Full Sample by Specification

	(1)	(2)	(3)	(4)	(5)
Eligibility	0.010	0.006	0.004	0.006	0.004
	(0.009)	(0.008)	(0.008)	(0.008)	(0.008)
	[0.230]	[0.501]	[0.652]	[0.455]	[0.574]
Country and survey-year FE	No	Yes	Yes	Yes	Yes
Religion	No	No	Yes	No	Yes
Rural	No	No	No	Yes	Yes
Effective observations	165,060	147,214	162,034	165,060	174,994
Bandwidth (months)	50.4	44.6	49.3	51.0	54.0
Control mean	0.666	0.665	0.666	0.666	0.665

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Each column is a separate local linear regression discontinuity estimate of the effect of eligibility on not being married before age 18. Robust bias-corrected standard errors clustered at the primary sampling unit level in parentheses, p-values in brackets. Effective observations within the MSE-optimal bandwidth. All columns use the same sample, women with rural residence and religion observed, so that differences between columns reflect the specification rather than the sample. Column (2) therefore differs from the fixed-effects estimate on all women reported in Table 3.

are added the sample is restricted to those respondents where residence and religion are observed. Without controls, the estimated effect is 1.9 percentage points and significant at the 5% level, it however does not survive correction for multiple testing (BH p = 0.117) and, as seen in column 2 of Table 2, falls to 0.6 percentage points once the women with missing religion are excluded. The estimate without controls is therefore sensitive to the sample, and I do not interpret it as evidence of an average effect. With controls, the estimate is 0.4 percentage points and identical to column (5) of Table 2.

This average null result matches findings in the existing literature. The difference-in-differences design across 17 countries using a continuous measure of local ban intensity by Wilson (2022) similarly finds no significant average effect on the probability of marrying before 18. Likewise, Collin and Talbot (2023) find detectable enforcement in only around 10% of countries and Batyra and Pesando (2021) find no decline in child marriage following the reform in four of six countries studied. However, my results show that this null average effect masks substantial country-level heterogeneity and that CMBs alter life-cycle outcomes even where they do not delay marriage.

Figure 3 presents the effect on marital timing graphically for the full sample and across all heterogeneity dimensions including controls and depicting their 95% confidence intervals. With controls, nine of the 26 subsamples show a significant effect at the 10% level. However, only one of them survives the correction for multiple testing (Table 3). Full results for all subsamples and both specifications are reported in Table A5.

Table 3: Effect of CMBs on Marital Timing: Full Sample and Significant Subsamples

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Robust bias-corrected RDD estimates of the effect of eligibility on not being married before age 18. Each column is a separate specification. Robust standard error in parentheses below are clustered at the primary sampling unit level. P-value and the BH adjusted p-value reported alongside. Both specifications include country and survey-year fixed effects. The specification without controls uses all women, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. Subsamples are shown if the effect is significant at the 10% level in either specification. The BH correction is computed within each specification across the full sample and all 26 subsamples.

Low Child Marriage Rate. In countries with a pre-reform child marriage rate below 20%,[30] CMB eligibility raises the probability of not marrying before age 18 by 6.8 percentage points. Figure 4 illustrates this graphically. The probability of not marrying before 18 shows no visible discontinuity at the cutoff in the full sample, whereas in countries with a low child marriage rate it jumps upwards for women born after the reform date. This corresponds to a reduction in child marriage of 39%, given that 17.5% of women in the control group marry before 18. This effect is significant at the 0.1% level, both with and without controls, and is the only one that survives the correction for multiple testing with controls (BH $p < 0.001$). While the result is robust to

[30] Albania, Egypt, Jordan, Maldives, Namibia and Tajikistan.

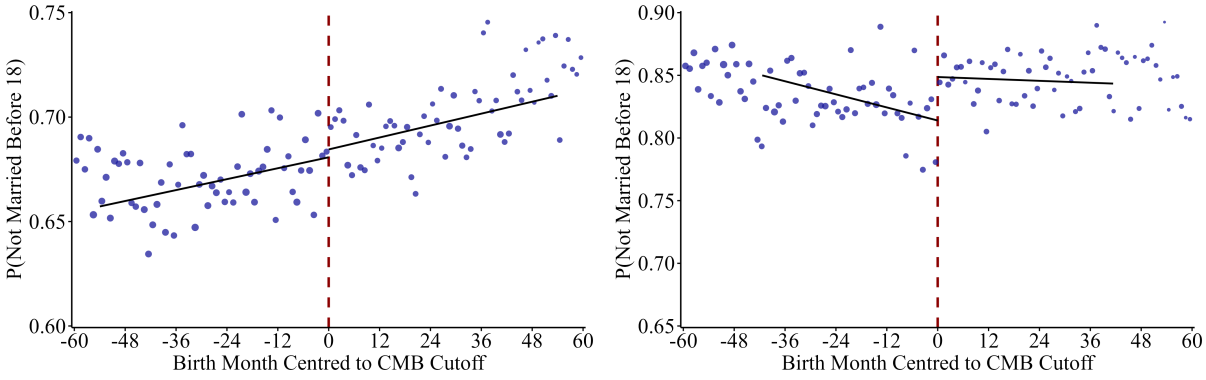

Figure 3: Effect of CMBs on Marital Timing: Heterogeneity

Notes: Each point is the robust bias-corrected local-linear RDD coefficient (Calonico et al., 2014) for the probability of not marrying before age 18 at the reform cutoff, estimated separately within each subsample. Horizontal bars are 95% confidence intervals. All regressions include country and survey-year fixed effects and control for rural residence and religion, and standard errors are clustered at the primary sampling unit level. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance. The upper block shows the full sample and individual-level subsamples, the lower block shows country-level subsamples.

alternative bandwidths and functional forms with controls, leave-one-out checks show that it is driven disproportionately by Tajikistan. It is also not detectable when using a coarser, annual running variable, meaning that the result depends on this finer timing. This suggests that monthly variation matters for identification, as an annual variable might blur a concentrated discontinuity by pooling eligible and ineligible women born in the same year. It is therefore the most credible effect in the sample, although it rests heavily on a single country and on monthly variation.

Figure 4: Marital Timing at the CMB Cutoff

(a) Full Sample **(b) Low Child Marriage Rate**

Notes: Each dot is the mean of the outcome in a birth-month bin, adjusted for country and survey-year fixed effects, rural residence and religion, and the line is a local linear fit on either side of the cutoff within the MSE-optimal bandwidth. The dashed vertical line marks the CMB cutoff. Women born to the right of the cutoff are eligible.

Suggestive Effects. Several further subsamples show significant effects at conventional levels but which do not survive the correction for multiple testing (see Table 3), and I read them as suggestive rather than confirmed.

The starkest contrast can be observed when distinguishing by the prevalence of informal unions, which the age at first union in the DHS does not separate from formal ones. In countries with a low share of informal unions at the time of CMB implementation, the effect is 2.0 percentage points, a relative reduction in child marriage of 5.7%. Conversely, in countries with a high share the effect is negative (-2.2 percentage points), an increase in child marriage of 6.8%. Both effects depend on country composition. A possible interpretation of this is that CMBs can only pose a binding constraint when informal unions cannot easily substitute formal ones, supporting the findings of Bellés-Obrero and Lombardi (2023).

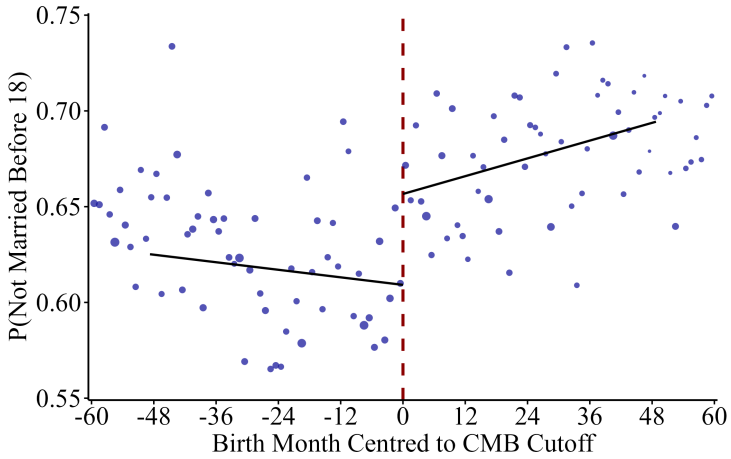

In countries where the previous legal minimum age was 16 or 17, CMB eligibility raises the probability of not marrying before 18 by 2.9 percentage points, a relative reduction in child marriage of 8.4%. This estimate is sensitive to the exclusion of Albania. In predominantly Muslim countries, the estimated effect is 3.2 percentage points and depends on the inclusion of Tajikistan, while among Muslim women across all countries it is smaller (2.1 percentage points) and only significant at the 10% level. In countries with low government effectiveness, the effect is 2.6 percentage points, but only significant at the 10% level. Finally, democracies and countries

with no previous minimum age are significant but reverse sign between the specifications with and without controls. As both rest on few countries and the No Previous Age estimate changes sign when a single country is excluded, I do not interpret them as evidence of a backfire effect.

Taken together, my results indicate that CMBs have the clearest potential to alter marital timing where child marriage was already comparatively rare before the reform, rather than attempting to change a well-established and highly common marital institution. The suggestive patterns for countries where informal unions are relatively less common and with a previous legal age of 16 or 17 point in the same direction but do not meet the same robustness. In other words, CMBs seem most likely to succeed when they accompany social change already underway rather than attempting to shift a well-established social institution through legislation alone.

Countries with a Strong First Stage. To study the life-cycle consequences of a delay in marriage, I additionally define a group of countries in which eligibility has a significantly positive effect on marital timing at the 10% level with controls, namely Benin, Nepal and Tajikistan.[31] In this group, eligibility raises the probability of not marrying before 18 by 4.8 percentage points with controls, a reduction in child marriage of 12.9%, and by 5.7 percentage points without. Figure 5 shows the resulting discontinuity at the cutoff. As the group is selected on its own first stage, its estimate is upward biased by construction, and it is therefore not part of the BH family. It serves only to condition the analysis in Section 5.2.

Figure 5: Marital Timing at the CMB Cutoff: Strong First Stage Countries

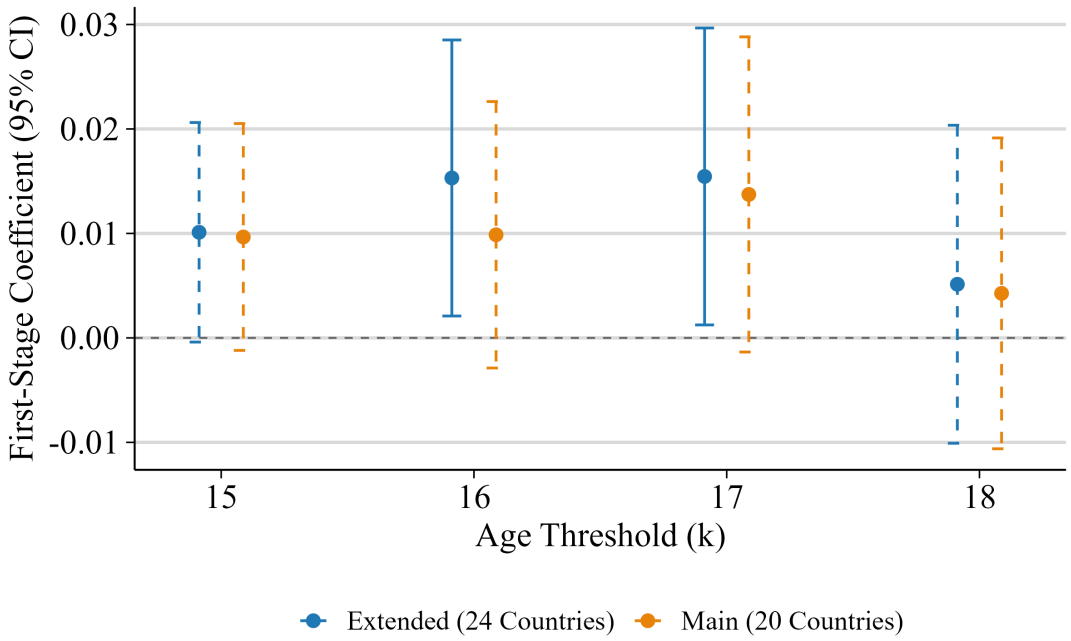

Notes: Benin, Nepal and Tajikistan. Each dot is the mean of the outcome in a birth-month bin, adjusted for country and survey-year fixed effects, rural residence and religion, and the line is a local linear fit on either side of the cutoff within the MSE-optimal bandwidth. The dashed vertical line marks the CMB cutoff. Women born to the right of the cutoff are eligible.

Effect by Age Cohort. The results above investigate whether CMB eligibility shifts marriage probability by age 18, the new legal minimum age of marriage. A separate question is whether the same eligibility delays marriage at younger ages even where it does not, on average, delay marriage by age 18. An effect at a younger age could for instance reflect that marriages are

[31] Full results by country in Table A4.

delayed to closer to the new legal age, out of fear of consequences if the gap is larger. For this purpose, I include, for each age threshold, only respondents who have already reached that age, which allows the inclusion of four additional countries that now have sufficient observations on each side of the cutoff, and I additionally provide results for the main sample of 20 countries for comparability. Figure 6 presents the effect of CMB eligibility on the probability of not being married at ages 15 to 18.[32] While the effect at age 18 itself, and at ages 20 and beyond, remains indistinguishable from zero throughout, I observe a significant positive effect at both ages 16 and 17 of 1.5 percentage points in the extended sample, corresponding to reductions of 9.8% and 6.4% in the share married by those ages, as well as a marginally significant effect of 1.0 percentage point at age 15 (11.9%). Within the main sample, the coefficients remain similar in size, but the effect at age 16 loses statistical significance and age 17 remains only marginally significant. This indicates that while CMBs do not delay marriage at the new legal age of 18 itself, they may have the potential to delay marriage among cohorts just below this age, although this effect is sensitive to the four additional countries that enter the sample once the age floor is relaxed below 18.

Figure 6: Effect of CMBs on Not Marrying Before Ages 15 to 18

Notes: Robust bias-corrected coefficients with 95% confidence intervals. Treatment is fixed at the true eligibility cutoff. Blue is the extended 24-country sample, orange the main 20-country sample. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance.

Given these findings, I re-estimate the effect of CMB eligibility on not being married by ages 16 and 17 for each subsample.[33] The results show a pattern distinct from that at age 18. Rural residence is significant at both ages in both samples, with effects of 2.3 to 3.0 percentage

[32] Table A6 provides complete results at these ages as well as at ages 20, 25 and 30.
[33] Full results in Table A7 and Table A8.

points, while the effect at age 18 is concentrated in countries with a low child marriage rate, which show no significant effect at ages 16 or 17. The most notable instability concerns countries with no previous minimum marriage age. At age 17, this subsample is highly significant in both samples but with opposite signs, a 7.5 percentage-point decline in the extended sample and an 11.0 percentage-point increase in the main sample. As this reversal follows from a change in country composition alone, heterogeneity at these ages should be interpreted with caution.

This pattern is worth reading alongside Wilson (2022), who finds a positive average effect on continuous age at marriage despite, like this paper, no significant average effect on the probability of marrying before 18. A continuous outcome, or a lower age threshold as used here, can pick up marginal delays that a single binary cutoff at 18 misses. Read together, the evidence across both papers suggests that CMB eligibility may delay marriage timing at the margin for some cohorts and countries, but does not prevent child marriage entirely.

5.2 Child Marriage Bans and Life-Cycle Outcomes

This section investigates effects of CMB eligibility on women's life-cycle outcomes across the four panels discussed in Section 3.2. I report reduced-form ITT estimates as the primary specification.[34] As the previous section established that the effect of eligibility on marital timing is on average and across most subsamples statistically insignificant and weak (F<10), scaling the reduced form by it would yield an unreliable, and potentially misleading, LATE, since under a weak instrument two-stage least squares estimates are biased towards OLS and have poor finite-sample properties (Bound et al., 1995). Every magnitude and significance level discussed below therefore refers to the ITT effect. Full results for each outcome and subsample, with BH adjusted p-values computed within each outcome across the full sample and all 26 subsamples, are reported in Appendix Section D.2. Table 4 presents reduced-form estimates for the full sample, and Figure 7 depicts them graphically. Figure 8 shows the same estimates for Low Child Marriage Rate countries and the countries with a strong first stage. The following paragraphs provide an overview of the results by panel.

Panel A: Fertility. On average, CMB eligibility has no significant effect on total fertility or on the probability of the first birth not occurring before age 18, which rises by 1.4 percentage points, a reduction of 2.9% in first births before 18. While the effect is null on average, I find positive effects on births after age 18 in seven of the 26 subsamples that survive the correction for multiple testing (eight at the 5% level without it), most of them subsamples with a null first stage. For instance, among women residing in rural locations (2.6 percentage points), among Christian women (4.0 percentage points), in predominantly Christian countries (4.2 percentage points) and also in predominantly Muslim countries (4.8 percentage points). All these effects survive the correction for multiple testing, however they should be read cautiously, as the estimate for predominantly Muslim countries changes sign in most leave-one-out exclusions. With controls,

[34] Fuzzy RDD estimates are reported in the appendix only for the two groups with a strong first stage and only for outcomes with a first-stage F-statistic of at least 10 (Table A22 and Table A23).

Table 4: Reduced-Form Effects on Life-Cycle Outcomes: Full Sample

Spousal Age Gap ≥ 5 yrs	-0.011 (0.010)	0.273	0.717	0.599	54.4	127,787

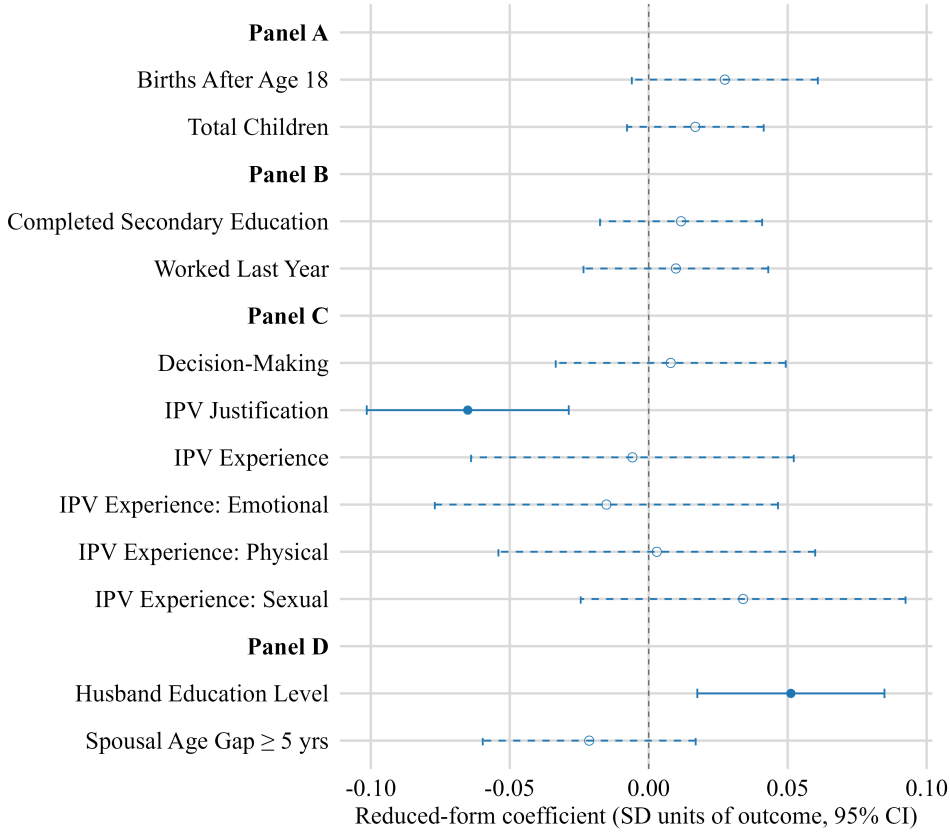

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected reduced-form RDD coefficients (SE in parentheses) of CMB eligibility on each outcome, using Calonico et al. (2014), for the full sample. The specification includes country and survey-year fixed effects and controls for rural residence and religion, and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples. Mean is the weighted mean of the outcome among untreated-side observations within the estimation bandwidth, BW the bandwidth in months. N is the total number of effective observations. Standard errors are clustered at the primary sampling unit level.

no subsample shows a robust effect on total children.

Panel B: Education and Employment. I find no significant effects on completed secondary education or on employment in the past year, in the full sample or credibly in any subsample. The only estimates that survive the correction for multiple testing with controls are in the Democracy subsample, where secondary education falls by 7.8 and employment by 9.4 percentage points. The subsample consists of only three countries and neither estimate remains significant when any one of them is excluded, so I do not interpret them. Without controls, employment is higher in Low Child Marriage Rate countries (7.5 percentage points), but not with controls.

Panel C: Decision-Making and IPV. This panel yields the clearest full-sample result. CMB eligibility reduces the justification of IPV by 2.1 percentage points, relative to a control mean of 0.196, a decline of 10.7%. The effect is significant at the 0.1% level, survives the correction for multiple testing, is similar without controls (2.2 percentage points) and holds under exclusion

Figure 7: Standardised Reduced-Form Life-Cycle Effects: Full Sample

Notes: Each point is the robust bias-corrected reduced-form (ITT) RDD coefficient (Calonico et al., 2014), standardised by the outcome's own standard deviation. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance. All regressions control for rural residence, religion, and country and survey-year fixed effects, and cluster standard errors at the primary sampling unit level.

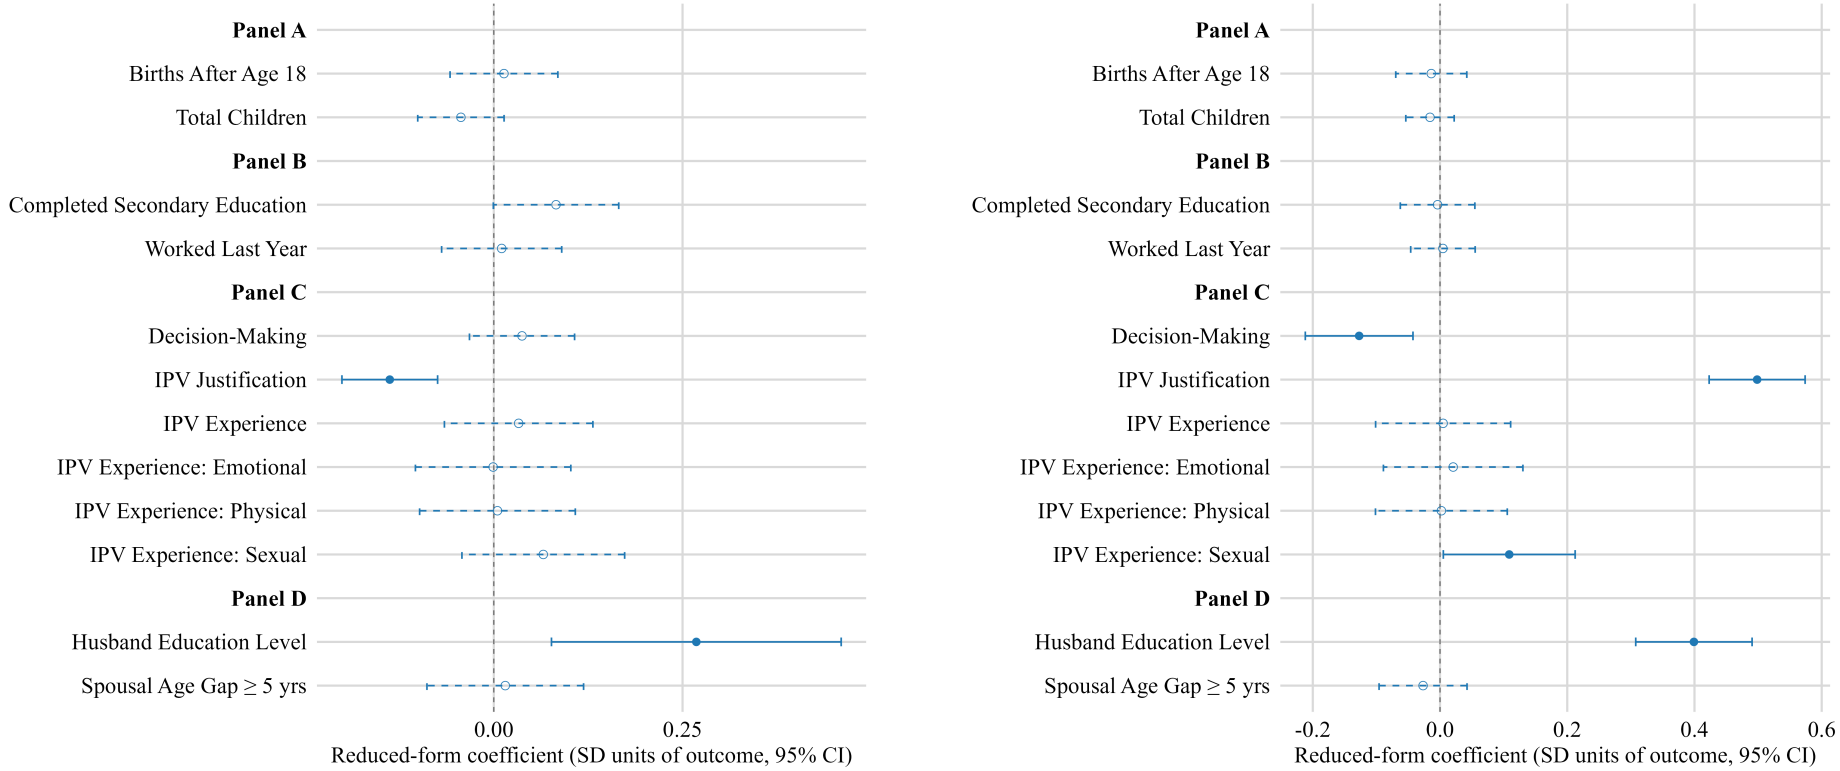

of most single countries.[35] This effect is also detectable across several subsamples. Among the 25 subsamples with a stable estimate, it is significant after the correction in nine, eight of them negative, with declines of 10 to 13% of the control mean in rural residence, anocracies, predominantly Muslim countries and among women with primary education.[36] Intra-household decision-making power and the experience of IPV, whether as combined measure or by type, being emotional, physical or sexual, are unaffected on average. A few subsample estimates for IPV experience are large but reverse sign across specifications and do not hold up to leave-one-out checks, which is why I do not interpret them. Further, as IPV is known to suffer from underreporting, with more educated and empowered women more likely to disclose (Cullen, 2023), any effect on stated IPV experience cannot be read directly as a change in incidence and theoretically an increase in reporting could mask a reduction in IPV itself.

Panel D: Marriage Market Outcomes. On average, eligible women marry more educated husbands, with the husband's education level rising by 0.051 points on the 0–3 scale, 3.6% of the control mean of 1.40. This effect survives the correction for multiple testing. As Table A20

[35]The effect is most sensitive to Guinea.

[36]The one positive estimate is for women aged 25 to 34.

Figure 8: Standardised Reduced-Form Life-Cycle Effects: Countries with a Significant First Stage

(a) Low Child Marriage Rate **(b) Strong First Stage Countries (Benin, Nepal, Tajikistan)**

Notes: Each point is the robust bias-corrected reduced-form (ITT) RDD coefficient (Calonico et al., 2014), standardised by the outcome's own standard deviation, in (a) Low Child Marriage Rate countries and (b) the countries with a significantly positive first stage. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance. The strong first stage group is selected on its own first stage and consists of three countries. Its estimates for IPV justification and husband education level reverse sign without controls and are not interpreted. All regressions control for rural residence, religion, and country and survey-year fixed effects, and cluster standard errors at the primary sampling unit level.

shows, this is driven by a lower probability of marrying a husband with only primary education (2.1 percentage points) and, more tentatively, a higher probability of marrying a husband with secondary (2.0 percentage points) or higher education (1.4 percentage points). However, the latter two do not survive the correction. The probability of marrying a husband with no education and the probability of a spousal age gap of five years or more are unaffected. The education level is significantly higher in 15 of the 26 subsamples, all surviving the correction, with increases of 4 to 10% of the control mean among Muslim women, women aged 18 to 24, urban and rural women and in anocracies. The exceptions are Democracy and high government effectiveness, which reverse sign without controls and which I do not interpret.

Given the inclusion of country and survey-year fixed effects, as well as the absence of an effect on women's own education or fertility, the effect on husband's education is unlikely to reflect a trend but rather a genuine effect of partner selection. This is further supported by the fact that the likelihood of getting married by age 30 is the same for eligible and non-eligible women (Table A6), which suggests no differential selection into the sample in which husband characteristics are observed. Importantly, throughout this analysis I cannot observe whether the shift in husband's education is favourable for the wife or not. Relative spousal education is sometimes used as a proxy for a wife's bargaining power, so a widening gap in the husband's favour could plausibly signal reduced rather than improved standing for the wife (Frempong and Stadelmann, 2024), while other evidence links more educated husbands to lower IPV perpetration, though this relationship is inconsistent across countries (Tsala Dimbuene et al., 2024). Given this ambiguity, I report the effect as a marriage-market outcome without characterising it as an improvement or a setback.

Life-Cycle Outcomes in Countries with a Significant First Stage. The results above do not condition on a delay in marriage, so they include effects where CMBs did not delay marriage. I therefore turn to the two groups in which eligibility delays marriage most clearly, countries with a low child marriage rate and the strong first stage group (Benin, Nepal and Tajikistan). In Low Child Marriage Rate countries, IPV justification falls by 4.0 percentage points relative to a control mean of 0.180, a decline of 22.2%. The effect survives the correction for multiple testing and is not driven by Tajikistan, although it loses significance when Jordan is excluded. The husband's education level rises by 0.20 points (10.5% of the control mean), driven by a higher probability of a husband with higher education (4.5 percentage points, 21.7%), but this estimate is unstable to the exclusion of single countries. Fertility, education, decision-making and IPV experience are unaffected. The fuzzy estimate for IPV justification is negative (-0.69, Table A22), but as the first stage is only 6.8 percentage points the fuzzy coefficient scales the reduced form by a small number and is inflated, so I treat it as indicative. In the group of countries with a first stage effect, the estimates that are consistent across specifications are a lower probability of a husband with no education (9.0 percentage points, 40% of the control mean), a higher probability of a husband with higher education (2.7 percentage points, 20%), lower decision-making power (3.8 percentage points, 11%) and a small increase in sexual IPV experience (2.7 percentage points).

As the group is selected on its first stage, consists of three countries and is not part of the BH family, I read these as descriptive. The corresponding fuzzy estimates for IPV justification are negative and significant (-0.57, Table A23) but equally inflated.

Taken together, these life-cycle results point to a channel distinct from delayed marriage itself. CMB eligibility reshapes marriage markets and attitudes towards IPV broadly, including in subsamples where the first stage is null. Among the 17 subsamples without a significant first stage with controls, IPV justification, births after age 18 and husband's education are each significant at the 5% level in at least six, far more than the roughly one expected by chance, although the subsamples overlap, so I read this as indicative. Fertility, education and employment are generally unaffected.

5.3 Robustness

This section examines whether the results above are driven by sample composition, by invalid identification, or by the specification. I focus on the first stage, since the interpretation of all life-cycle results rests on it, and on the two groups the paper conditions on, Low Child Marriage Rate and the strong first stage countries. I first vary the estimation sample, restricting it to ever-married women and to marriages that are not pregnancy-driven. I then test the validity of the design, using a manipulation test of the running variable, a covariate balance test and placebo tests. Finally, I vary the specification, using age at first marriage as a continuous outcome, an annual running variable, alternative bandwidths and a local quadratic polynomial, and re-estimate the main results dropping one country at a time. The BH correction for multiple testing is applied throughout the main results and described in Section 5. All tables and figures referenced here are in Appendix Section D.3.

Ever-Married Subsample. I first restrict the sample to ever-married women, including those who are separated, divorced or widowed, to isolate the population for whom the treatment margin is actively binding. This rules out that pooling women who for unknown reasons never married biases the effect of the CMB on the probability of marrying at age 18 or later. Table A24 reports the full results and Figure A2a displays the significant subsamples. The overall first stage remains weak (0.012, p=0.14), but seven subsamples are significant at the 10% level, none of which survives the BH correction. These reproduce Low Child Marriage Rate (0.030), Previous Age 16/17 (0.027) and low informal unions (0.026) from the main estimation and add women aged 18–24 (0.045), rural residence (0.023), women with primary education (0.021) and anocracies (0.019). Restricting to ever-married women therefore does not itself recover a strong instrument, but it reproduces the main heterogeneity pattern.

Excluding Pregnancy-Driven Marriage. Since a pregnancy-driven marriage plausibly does not respond to a CMB the way other marriages do, I re-estimate the first stage excluding women whose first birth occurred within the 12 months preceding marriage or the first 8 months following it, which drops 10.3% of the full sample. Some child marriage legislation exempts marriages linked to pregnancy or childbirth, so these marriages may occur regardless of the CMB.

Further, the negative consequences of child marriage on women's human capital accumulation and life-cycle outcomes are here contrasted with evidence showing that marriage can benefit children through greater parental resources (Kearney and Levine, 2017; Yan, 2025). The measure cannot perfectly identify pregnancy-driven marriages, but it substantially reduces the likelihood that observed marriages were directly linked to a pregnancy. Women with a pregnancy-driven marriage marry on average about four months earlier than the others (18.4 against 18.7 years in the five-year bandwidth), but only slightly more often before 18 (43.6% against 40.7%), so excluding them removes a group that is only marginally more exposed to the reform margin. Table A25 reports the full results and Figure A2b displays the significant subsamples. The overall first stage remains null (0.007, p=0.39), but ten subsamples are significant at the 10% level and six survive the BH correction. The suggestive effects of the main estimation strengthen, in particular for predominantly Muslim countries (0.059) and in the opposite directions for low and high informal unions (0.021 and −0.034), while Low Child Marriage Rate (0.034) and Previous Age 16/17 (0.024) remain significant. Two subsamples that are not significant in the main estimation become so, Medium Child Marriage Rate (0.071) and Previous Age 14/15 (0.103). As a direct complement, the first stage among women whose marriage was potentially caused by pregnancy is null (-0.016, p=0.48), consistent with these marriages being driven by the pregnancy itself rather than by the legal minimum age, and indicating that the reform does not detectably shift timing for this group either.

Manipulation Test. I run Cattaneo et al. (2020)'s density test on the running variable, pooled and by country.[37] The pooled test rejects continuity at the 1% level, a validity concern I do not want to understate, and nine countries are flagged at the 10% level after a BH adjustment.[38] However, excluding them does not strengthen the first stage with controls (0.007 against 0.004 at baseline, p=0.45), but it removes the full-sample estimate without controls (0.005 against 0.019), which supports not interpreting that estimate. A separate check shows only a modest excess of respondents reporting the same month for their birth and marriage (10.3% against 8.3% expected), concentrated in the same countries. Besides misreporting, this could reflect known imputation mechanisms when the respondent cannot recall either date. The Low Child Marriage Rate estimate is robust to a donut hole of 1 and 3 months around the cutoff, but not of 2 or 6 months. The strong first stage group is robust to donuts of up to 6 months. Both checks are consistent with a recall or imputation mechanism rather than intentional misreporting.

Covariate Balance. As I cannot rule out that another policy coincides with the reform cutoff, I test for continuity at the cutoff in the individual-level covariates I include as controls, namely rural residence and the two predominant religions, Christian and Muslim (Table A28). Rural residence and Christian women are balanced, while the share of Muslim women is imbalanced at the 10% level (0.019, p=0.09).

Continuous Age at First Marriage. I re-estimate the effect on age at first marriage in months,

[37] See Table A26 for the density table, Figure A3 and Table A27 for the country-level heaping table.
[38] Benin, Ghana, Comoros, Guinea, Tajikistan, Sierra Leone, Madagascar, Mozambique, Liberia.

addressing the concern that the binary indicator collapses within-category variation in marital timing (Table A29). Because age at first marriage is only observed for ever-married women, this restricts the estimation sample. With controls, the full-sample effect is indistinguishable from zero (1.1 months, p=0.22), consistent with the main specification. CMB eligibility delays age at first marriage by 5.5 months in Low Child Marriage Rate countries (p=0.002) and by 3.7 months among women aged 18–24 (p=0.005), the latter not evident in the binary specification. The estimate for Previous Age 16/17 is positive with controls (3.3 months) but negative without (−3.9 months). When interpreting these results it should be kept in mind that this check uses a different outcome and sample. It does show, however, that the direction of the main effects is not an artefact of the binary threshold.

Annual Running Variable. I collapse the running variable to years since the reform, in line with Collin and Talbot (2023) (Table A30). The full-sample first stage is unchanged (0.002). Low Child Marriage Rate, the most robust effect among my results, loses significance (0.004, p=0.81), and so does the strong first stage group (0.020), whereas Previous Age 16/17 strengthens (0.052, p<0.001). This is important, as it means that the result for the countries with a low child marriage rate depends on the finer monthly timing.

Bandwidth Selection and Functional Form. I re-estimate using Calonico et al. (2014)'s CER-optimal bandwidth and a local quadratic polynomial in place of the baseline MSE-optimal bandwidth and local linear specification (Table A32 and Table A33). The full-sample estimate stays insignificant under both (0.012 and 0.006), so neither under-fitting nor the choice of bandwidth explains the null average first stage. Low Child Marriage Rate (0.041 and 0.038) and the strong first stage group (0.046 and 0.037) remain significant under both. Previous Age 16/17 and predominantly Muslim countries remain significant under the CER-optimal bandwidth (0.032 and 0.034) but only at the 10% level under the quadratic specification (0.023 and 0.027). The CER-optimal bandwidth also yields a significantly negative estimate for medium child marriage rate countries (−0.072) and an implausible one for Democracy, which I do not interpret.

Fixed Bandwidth. As a check independent of any bandwidth selector, I re-estimate the first stage at fixed bandwidths of 2 to 10 years (Table A31 and Figure A4). Low Child Marriage Rate and the strong first stage group are significant at the 5% level at every bandwidth, the most uniformly robust results. Previous Age 16/17 requires at least five years, while predominantly Muslim countries are significant between three and six years and fade at ten. The full sample remains null throughout.

Placebo Tests. I estimate the first stage at fake cutoffs 12 and 24 months before and after the true cutoff, on one side of the true cutoff only. None of the twelve estimates for the full sample, Low Child Marriage Rate and the strong first stage group is significant at the 5% level, while the estimates at the true cutoff stand out for the two groups (Figure A5). Moving the legal age threshold between 15 and 20 shows the same for Low Child Marriage Rate, which is only significant at 18, whereas the strong first stage group is significant at 18 and at 20 (0.062), and the full sample is only significant at 16 (−0.044) (Figure A1).

Leave-One-Country-Out. I re-estimate the effect on marital timing and on every outcome significant with controls, dropping one country at a time, for the full sample, Low Child Marriage Rate and the strong first stage group (Figure A6, Figure A7 and Figure A8). In the full sample, IPV justification is significant under exclusion of 17 of the 20 countries and most sensitive to Guinea, while the husband's education level is significant under all 20. For Low Child Marriage Rate, the first stage remains significant when any country other than Tajikistan is excluded, but falls to zero without Tajikistan, which is also part of the strong first stage group. The effects on IPV justification and husband's education in this subsample remain significant when five of the six countries are excluded in turn, but the husband's education estimate is unstable in size, as excluding Jordan inflates it beyond half of the scale's range. In the strong first stage group, the first stage is significant under every exclusion, but its life-cycle estimates collapse when any single country is excluded and I read them as descriptive.

5.4 Limitations and Future Research

Limitations. Several limitations should be noted. First, and most fundamentally, the first stage is weak in the full sample and in most subsamples, so the paper's causal claims rest on reduced-form estimates rather than fuzzy RDD LATE estimates throughout. Of the nine subsamples with a first stage significant at the 10% level with controls, only one, Low Child Marriage Rate, survives correction for multiple testing across the 27 estimates. The others are reported as suggestive rather than confirmed for this reason alone, independent of the country-level fragility discussed next. Even this result is itself fragile, as it is disproportionately driven by a single country and loses significance when the running variable is collapsed to years.

Second, the data themselves carry the usual limitations of retrospective, self-reported survey data. Birth and marriage dates are recalled rather than drawn from administrative registers, and the manipulation test detects heaping in the running variable in nine of twenty countries, most plausibly driven by enumerator or respondent date imputation rather than strategic manipulation, but not fully distinguishable from it in survey data alone. The IPV experience module is available only for a subset of DHS countries and rounds, so those specific outcomes are estimated on a smaller and potentially non-random subsample of countries and years. Husband characteristics are only observed for the current husband, which could understate effects on marriage-market outcomes if women who married substantially older men are disproportionately widowed or remarried by the time of survey. Individual characteristics such as education and religion, are measured at the time of survey rather than at the time of marriage, and while the narrow estimation bandwidth (typically three to five years around the cutoff) makes it plausible that these are close to predetermined, I cannot rule out that some respondents' circumstances changed between the CMB reform and the survey in ways correlated with treatment.

Third, while the cross-country design improves external validity relative to a single-country study, it necessarily abstracts from country-specific mechanisms that plausibly shape reform effectiveness: local enforcement capacity, administrative implementation, and existing social

norms around marriage age all vary across the sample, both across and within countries. While I attempt to capture these via country-level subsamples, this could mask regional heterogeneity. For instance, one dimension I do not currently exploit is ethnic and customary variation in marriage practices, in particular bride-price and dowry systems, which the economics literature on marriage markets (e.g. Corno et al. (2020) on bride price and drought-driven child marriage) links directly to the economic incentives underlying early marriage. Linking DHS clusters to ethnic-group-level marriage-custom data would allow a direct test of whether CMB effectiveness varies with the prevailing bride-price regime.

Fourth, this paper only considers effects on women. While girls and women are disproportionately affected by child marriage and its consequences, insights on the effects on boys and men would complement the findings of this paper. Extending the analysis to men is not straightforward, however, as the legal minimum age of marriage, and hence the timing of reform, often differs by sex, requiring CMB eligibility to be recoded separately for each country. The DHS Men's Questionnaires are also considerably less comprehensive than the Women's Questionnaires used throughout this paper, limiting the range of outcomes available for a male sample.

Finally, the outcomes studied here are downstream life-cycle outcomes, not direct measures of enforcement or compliance behaviour. I can document where the first stage is strong or weak, but I do not directly observe why. In other words, I cannot distinguish whether effects in the respective subsamples are due to administrative capacity, awareness campaigns, community-level enforcement, or shifting social norms. IPV outcomes are self-reported attitudes and experiences rather than objective incidence, a well-documented measurement concern in the domestic violence literature more broadly.

Future research. These limitations point to several avenues for future research. Administrative or registry-based birth and marriage data, where available, would sidestep the recall and heaping concerns inherent to retrospective survey data and allow a sharper manipulation test. Marriage histories that record more than the current union would also help establish whether the husband-characteristics results are understated by remarriage. Linking the existing sample to ethnic-level marriage-custom data would allow future work to test bride-price and dowry regimes as moderators of CMB effectiveness directly. Sub-national or district-level measures of state capacity and enforcement, where available, would allow a more precise test of the enforcement-gap mechanism than the rural versus urban or country-level institutional indices used here. Recoding CMB eligibility separately by sex and drawing on the DHS Men's Questionnaires, despite their more limited scope, would allow a direct test of whether CMBs affect marriage timing and downstream outcomes for men in the same way as for women. Longer panel follow-up would let future work test whether the paper's most robust reduced-form findings, on husband's education and attitudes towards IPV, persist into second-generation outcomes such as children's schooling and health. Finally, as additional DHS rounds become available, several of the underpowered subsamples identified here could be re-estimated on a larger and more stable sample.

6 Conclusion

Child marriage remains a major policy concern, yet evidence on when CMBs actually work, and on whether they change women's broader life trajectories, has remained limited. This study set out to determine, first, whether CMBs, reforms setting the minimum legal age of marriage at 18 without parental-consent exceptions, have the potential to alter marital timing under specific socio-economic conditions, and second, whether they can alter women's life-cycle outcomes even when marital timing remains unchanged. This study provides, to my knowledge, the most comprehensive cross-country evaluation of CMBs to date, covering reforms enacted between 1995 and 2023 by combining harmonised legal reform data from the WORLD Policy Analysis Center with nationally representative DHS data from 20 countries, and exploiting variation in reform eligibility across birth cohorts through a robust bias-corrected RDD.

Excluding reforms that retain parental-consent exceptions matters in practice, as many countries that nominally set a minimum age of 18 still permit marriage below it with parental permission, leaving the reform without any binding force in these cases. This study contributes to the ongoing discussion in development and gender economics, among other disciplines, of when legal reforms translate into actual behavioural change by focusing on reforms that impose a binding constraint on the age of marriage. My results confirm the existing finding that CMBs do not delay marriage on average, but establish two novel findings the literature has not yet documented.

First, this average null effect masks meaningful heterogeneity. Where child marriage was already comparatively rare before the reform, CMB eligibility measurably reduces it further, by 39% relative to the child marriage prevalence observed in the control group. This effect survives correction for multiple testing, but it is driven disproportionately by one country and depends on the monthly timing of birth cohorts. I document similar patterns in countries where informal unions are less common, where the previous legal minimum age was already close to 18, and in predominantly Muslim countries, but treat them as suggestive rather than confirmed, since none of these subsamples survives correction for multiple testing. Further, while I find no average effect on marriage at 18, the new legal age, I find suggestive evidence of an effect at ages 16 and 17 in an extended 24-country sample, though only the effect at age 17 remains marginally significant in the paper's main sample. I find no robust evidence that individual characteristics, including rural location, religion and education, moderate CMB effectiveness.

Second, and independent of whether marriage is delayed, CMB eligibility reshapes marriage markets and attitudes towards IPV. Even in the complete pooled sample, where the reform has no detectable effect on marriage timing, CMB eligibility lowers the justification of IPV by 11% and raises the education of the husband a woman goes on to marry. Both effects survive correction for multiple testing and appear even in subsamples where the first stage is entirely null. In countries with a low child marriage rate, where marriage is delayed, the decline in IPV justification is even larger, at 22%, suggesting that positive effects are enhanced when the CMB binds. Importantly, whether the shift in husband's education is welfare-improving cannot be assessed, but it shows

that CMBs can alter women's life-cycle outcomes beyond marital timing. At the same time, I find no generalisable effect on women's own education, employment, or fertility, or on the experience of IPV itself.

A number of limitations should be noted. The first stage is weak throughout this paper, so the causal claims rest on reduced-form ITT estimates rather than fuzzy RDD LATE estimates, which would be imprecisely estimated given this weakness, and the one confirmed first-stage result rests heavily on one country. Administrative data in place of self-reported data, a longer panel, and considering the smaller male DHS sample would each strengthen this evidence, particularly for the results on husband's education and IPV attitudes that do not depend on the fragile first stage.

Notwithstanding these limitations, this study points to the specific margin at which policy operates. While CMB legislation cannot overturn a marriage practice sustained by broader social and economic conditions, it can reinforce a shift already underway, and it operates on the marriage market through channels other than its stated goal of delayed marriage. Policy design that treats a CMB as uniformly binding, or writes it off wherever it fails to move the headline marriage-timing statistic, misses both. Legal reform is thus best understood in this context as a complement to social change already in motion, not a substitute for it. If the goal is to alter marriage age itself, a minimum-age law on its own is unlikely to be sufficient. Its effectiveness depends on the conditions it meets, not on the law alone. Even where those conditions are not yet in place, however, this paper shows the law is not without consequence. It still shifts the marriage market and the attitudes surrounding it, an effect distinct from, and independent of, its stated goal.

A Declaration on the use of AI tools

In the preparation of this paper "Beyond Average Effects: The Uneven Promise of Child Marriage Bans", I used Claude (Anthropic) in the following ways:

1. Language editing: I used the tool to edit my writing, including proofreading and reformulation. The aim was to reduce typos and grammar mistakes, as English is not my first language, and to improve readability, concision and organisation. After every use, I reviewed and edited the content as needed.

2. Coding assistance: I used the tool to help me write and debug R scripts, particularly for the comprehensive robustness tests I conduct. The empirical strategy, main estimation pipeline, and all reported results are my own work.

3. Literature research: I used the tool to conduct literature research using specific search terms.

All underlying analysis, findings, and interpretation are my own. I take full responsibility for the content, analysis, and conclusions of this paper, including all text and code produced with AI assistance, which I have reviewed and verified.

B Literature

B.1 Literature Overview

Appendix Table A1 provides an overview of the most relevant peer-reviewed articles for this analysis, considering the effects of child marriage reforms on women's socioeconomic outcomes, including health, education, and agency. Column *CMB* details whether the authors exclusively analyse child marriage reforms that set the legal minimum age at marriage for women at 18 years regardless of parental consent. Column *N* presents the number of countries included, with those above 17 including countries both with and without CMBs.

Table A1: Summary of Literature on Child Marriage Reforms and Socioeconomic Outcomes

Article	CMB	N	Data	Model	Outcomes
Batyra and Pesando (2021)	No	6	DHS, MICS, PROSPERED	Fuzzy RDD	Marriage
Bellés-Obrero and Lombardi (2023)	Yes	1	Ministry	Two-way FE DiD	Marriage, fertility, school enrolment
Collin and Talbot (2023)	Mixed	121	DHS, MICS, WORLD	RDD	Marriage
Kidman et al. (2024)	Yes	16	DHS, WORLD	Two-way FE	Marriage, fertility
Kim et al. (2013)	Mixed	115	Country level	FE time series	Fertility
Le et al. (2025)	Yes	17	DHS, WORLD	Generalized DiD	Infant mortality
Maswikwa et al. (2015)	Yes	12	DHS, GRID, WORLD	Multivariate log binomial, Log Poisson	Marriage, fertility
McGavock (2021)	No	1	DHS	DiD, event study	Marriage
Omidakhsh and Heymann (2020)	Yes	5	DHS, WORLD	DiD	IPV
Rokicki (2021)	No	1	DHS, WORLD	DiD, Synthetic control methods	SRH
Wilson (2022)	Yes	17	DHS	DiD	Education, employment, marriage, fertility

Notes: This table outlines literature directly relevant to the study, specifically focusing on CMBs. The overview is limited by the search parameters employed and will be expanded in ongoing work. "CMB" indicates whether the study explicitly analyses reforms setting the minimum marriage age at 18 regardless of parental consent. For studies defining distinct treatment and control groups, the country count N refers to treatment countries only. Abbreviations: Difference-in-Differences (DiD), Fixed-Effects (FE), Multiple Indicator Cluster Surveys (MICS).

		n	223,741	121,298	102,443

Descriptive statistics for the full sample and by reform eligibility for a bandwidth of 5 years on either side of the cutoff. All country-level variables are author-constructed, either merged in from outside the DHS and matched to each country's policy-introduction year (Polity IV score matched to the nearest available year for Regime Type) or built from the women of the five birth cohorts preceding the reform (informal unions, rural share, predominant religion). *Abbreviations:* World Bank (WB), World Development Indicators (WDI), Worldwide Governance Indicators (WGI), Standard Deviation (SD).

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on not marrying before age 18, estimated separately for each country with survey-year fixed effects, without and with controls for rural residence and religion. The remaining columns show the classification used for the country-level subsamples. Child marriage rate is low below 20%, medium 20 to 40% and high above 40%. Informal unions, rural share and government effectiveness are split at the cross-country median, previous min. age is the legal minimum age before the CMB, religion is the majority religion and regime follows the Polity score (Maldives has none). ‡ Countries with a significantly positive first stage at the 10% level with controls, which form the strong first stage group. u Unstable estimate (larger than half the standard deviation of the outcome), reported but not interpreted.

D Complete Results

D.1 Effect of CMBs on Not Marrying Before Age 18

Figure A1: First Stage: Sensitivity to the Legal Age Threshold (Ages 15–20)

Notes: Each point is the robust bias-corrected local-linear RDD coefficient (Calonico et al., 2014) for the probability of not marrying before age 18 shown on the x-axis, estimated separately at each threshold within each subsample. Vertical bars are 95% confidence intervals. All regressions control for rural residence, religion, and country and survey-year fixed effects, and cluster standard errors at the primary sampling unit level. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance. Panels report the full sample and the four subsamples with a significant first stage at the age-18 cutoff in the main specification.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on not marrying before age 18, using Calonico et al. (2014). Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples, computed separately for each specification. Mean refers to the weighted control group mean of the outcome within the estimation bandwidth. N is the number of effective observations within the MSE-optimal bandwidth on both sides of the cutoff. BW: Bandwidth (months).

D.1.1 Effect at Ages 16 and 17

Table A6: Effect of CMBs on Marrying by Age Threshold: 24-Country vs. 20-Country Sample

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on births after age 18, using Calonico et al. (2014). Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples, computed separately for each specification. N is the total number of effective observations within the MSE-optimal bandwidth.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on the probability of experiencing any form of IPV, using Calonico et al. (2014). Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples, computed separately for each specification. N is the total number of effective observations within the MSE-optimal bandwidth.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on husband education level, using Calonico et al. (2014). Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples, computed separately for each specification. N is the total number of effective observations within the MSE-optimal bandwidth.

Table A20: Effect of CMBs on Husband Education by Level

	Without Controls			With Controls

Higher	0.027*[a] (0.011)	–	36,268	0.027* (0.012)	–	35,155

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on the probability that the husband has the respective education level (none, primary, secondary or higher), using Calonico et al. (2014). Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples, computed separately for each specification and outcome. The strong first stage countries are not part of this family, so no BH p is reported for them. N is the total number of effective observations within the MSE-optimal bandwidth. [a] Estimate after dropping country-survey cells observed on one side of the cutoff only, used because the estimate on the full sample was implausible (larger than half the outcome's standard deviation).

Husband Education Level	–	5.6	18,278	0.675 (0.986)	15.8	25,658
Spousal Age Gap ≥ 5 yrs	2.410*** (0.556)	25.4	35,560	–	5.9	37,016

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Fuzzy RDD estimates (SE in parentheses) of the effect of not marrying before age 18 on each outcome for compliers in countries with a low child marriage rate, using Calonico et al. (2014), with eligibility as the instrument. F is the first-stage F-statistic at the fuzzy bandwidth of each outcome, and estimates are reported only where it is at least 10. Because the first stage is small, the fuzzy estimates scale the reduced form by a small number and are inflated, and they should be read as indicative. The first stage of this subsample, the effect of eligibility on marital timing, has an F-statistic of 11.7 without controls and 26.3 with controls. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion. N is the total number of effective observations.

Table A23: Fuzzy RDD Effects of Not Marrying Before Age 18: Strong First Stage Countries

	Without Controls			With Controls		
Outcome	Estimate (SE)	F	N	Estimate (SE)	F	N
Births After Age 18	-0.133 (0.276)	12.4	30,883	–	6.5	27,951
Total Children	-0.13 (0.74)	11.4	28,872	-0.01 (0.68)	13.2	34,479
Completed Secondary Education	0.056 (0.230)	30.3	46,483	-1.173*** (0.252)	79.0	46,470
Worked Last Year	-0.006 (0.257)	17.6	41,043	-0.036 (0.271)	17.0	39,117
Decision-Making	–	4.9	25,447	-0.286 (0.195)	10.1	32,203
IPV Justification	-0.564* (0.233)	13.7	30,883	-0.570* (0.245)	12.1	31,573

IPV Experience: Emotional	–	0.4	8,652	–	0.3	8,819
IPV Experience: Physical	–	1.1	12,845	–	1.4	13,019
IPV Experience: Sexual	–	0.4	10,047	–	0.5	10,274
Husband Education Level	–	3.2	28,332	1.630 (1.151)	10.3	31,696
Spousal Age Gap ≥ 5 yrs	–	0.7	32,501	-0.562 (0.547)	17.7	35,443

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Fuzzy RDD estimates (SE in parentheses) of the effect of not marrying before age 18 on each outcome for compliers in the countries with a strong positive first stage, Benin, Nepal and Tajikistan, using Calonico et al. (2014), with eligibility as the instrument. These countries are selected on a significantly positive effect of eligibility on marital timing in the specification with controls, so the p-values are conditional on this selection. F is the first-stage F-statistic at the fuzzy bandwidth of each outcome, and estimates are reported only where it is at least 10. Because the first stage is small, the fuzzy estimates scale the reduced form by a small number and are inflated, and they should be read as indicative. The first stage of this subsample, the effect of eligibility on marital timing, has an F-statistic of 15.3 without controls and 11.0 with controls. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion. N is the total number of effective observations.

Low Gov. Effectiveness	0.023+ (0.014)	0.597	0.083	0.248	55,629	40.8
High Gov. Effectiveness	-0.001 (0.010)	0.755	0.903	0.940	82,480	52.4

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on not marrying before age 18, using Calonico et al. (2014), estimated excluding marriages motivated by pregnancy. All regressions include country and survey-year fixed effects and control for rural residence and religion. BH p is the BH adjusted p-value within the family of the full sample and all 26 subsamples. Mean refers to the weighted control group mean of the outcome within the estimation bandwidth. N is the number of effective observations within the MSE-optimal bandwidth on both sides of the cutoff. BW: Bandwidth (months).

Figure A2: Ever-Married Women and Excluding Pregnancy-Driven

(a) Ever-Married Women **(b) Excluding Pregnancy-Driven Marriages**

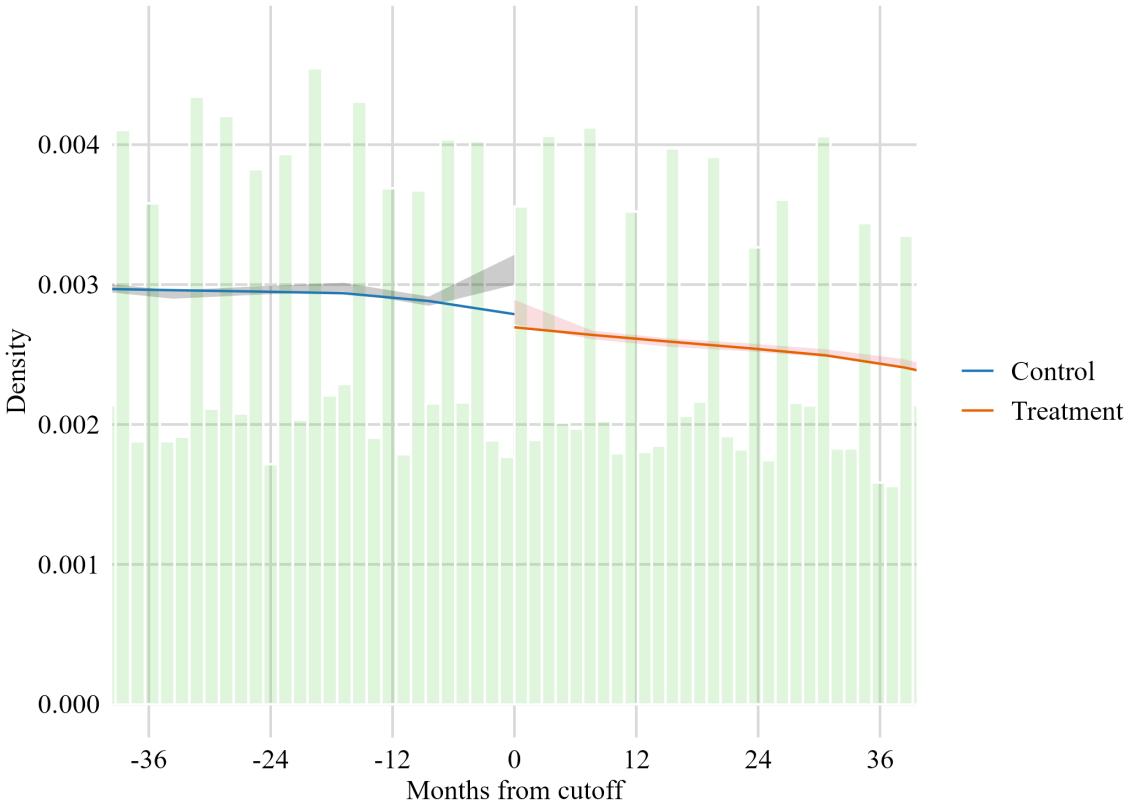

Notes: Both figures feature only subsamples that are statistically significant at the 10% level, in panel (a) for women that were ever married and in panel (b) excluding marriages that were motivated by pregnancy. Each point is the robust bias-corrected local-linear RDD coefficient (Calonico et al., 2014) for the probability of marrying at or after the legal minimum age (i.e., not marrying before age 18) at the reform cutoff, estimated separately within each subsample. Horizontal bars are 95% confidence intervals. All regressions control for rural residence, religion, and country and survey-year fixed effects, and cluster standard errors at the primary sampling unit level. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote significance only at the 10% level.

Table A26: Manipulation Test: Pooled Density Test

Robust T	p-value	N (Effective, Left / Right)	N (Raw, Left / Right)
-4.26	<0.001	50,050 / 42,898	475,338 / 211,717

Notes: Cattaneo et al. (2020)'s manipulation test on the running variable at the reform cutoff, pooled across all countries. N (Effective) is the number of observations used by the local polynomial density estimator on each side of the cutoff; N (Raw) is the full sample on each side.

Figure A3: Manipulation Test: Density of the Running Variable at the Cutoff (Pooled Sample)

Notes: Estimated density of the running variable (months from the reform cutoff) on either side of the cutoff, pooled across all countries, using Cattaneo et al. (2020)'s local polynomial density estimator. Shaded regions are 95% confidence bands. A discontinuity in the density at the cutoff would indicate manipulation or sorting of the running variable; Appendix Table A26 reports the corresponding formal test.

Table A27: Manipulation Test: Country-Level Heaping Collision Check

Country	Cutoff Month	Heaping Ratio	t_{jk}	p-value (BH)	Flagged
Benin	Sep	0.86	-8.70	<0.001	Yes
Ghana	Jan	1.30	-8.25	<0.001	Yes
Comoros	Jan	1.30	5.73	<0.001	Yes
Guinea	Sep	0.86	-4.53	<0.001	Yes
Tajikistan	Jan	1.30	3.98	<0.001	Yes
Sierra Leone	Sep	0.86	-2.88	0.013	Yes
Madagascar	Aug	0.97	-2.64	0.024	Yes
Mozambique	Dec	0.88	2.31	0.052	Yes
Liberia	Feb	1.05	2.07	0.086	Yes
DR Congo	Jan	1.30	1.78	0.150	No
Namibia	Jul	1.00	-1.64	0.185	No
Nepal	Sep	0.86	-1.54	0.206	No
Kenya	May	1.08	-1.33	0.280	No
Jordan	Apr	1.11	-0.66	0.669	No
Albania	May	1.08	0.64	0.669	No
Ethiopia	Jul	1.00	-0.58	0.669	No
Egypt	Jun	1.04	0.57	0.669	No
Maldives	Jan	1.30	-0.48	0.699	No
Gambia	Jul	1.00	-0.31	0.755	No
Togo	Jul	1.00	-0.31	0.755	No

Notes: Per-country Cattaneo et al. (2020) density test at each country's own reform cutoff. Cutoff Month is the calendar month the country's cutoff falls on. Heaping Ratio is the ratio of births in that calendar month to the count expected under a uniform distribution across months, pooled across the full sample. p-values are Benjamini-Hochberg adjusted across the 20 countries; Flagged indicates significance at the 10% level after adjustment.

Table A28: Balance of Covariates at CMB Cutoff

Covariate	Estimate (SE)	p-value	N (Left)	N (Right)	BW
Rural	0.0042 (0.0106)	0.692	129,589	107,794	64.6
Christian	-0.0162 (0.0105)	0.124	96,462	84,683	49.1
Muslim	0.0187^{+} (0.0111)	0.091	74,060	66,955	38.7

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Each row is a separate robust bias-corrected local-linear RD estimate (Calonico et al., 2014) of the listed covariate on the running variable at the reform cutoff, for the full sample, with no additional controls. Standard errors clustered at the primary sampling unit level in parentheses. BW: Bandwidth (months).

High Gov. Effectiveness	1.421 (1.263)	60,090	40.8	0.145 (1.254)	61,124	41.4

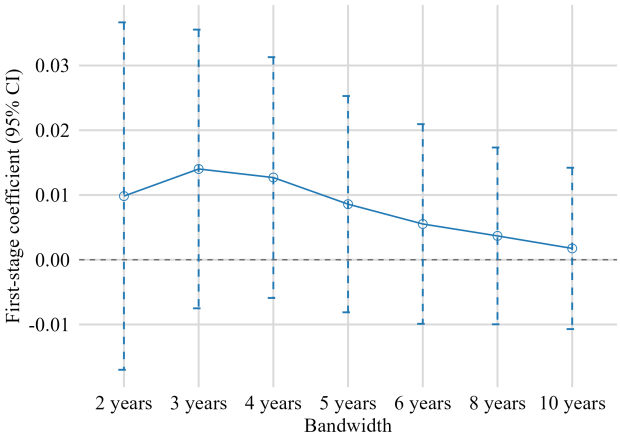

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on age at first marriage in months, using Calonico et al. (2014). The outcome is constructed directly from month-level marriage- and birth-date components, not by rescaling the years variable. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. Since age at first marriage is only observed for ever-married respondents, the estimation sample is restricted relative to the binary first stage and is not directly comparable to it. N is the total number of effective observations within the MSE-optimal bandwidth. BW: Bandwidth (months). [u] Unstable estimate (still larger than half the standard deviation), reported but not interpreted.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Each cell is a separate robust bias-corrected first-stage RDD coefficient (Calonico et al., 2014), estimated at the fixed bandwidth (h = b, not data-driven) shown in the column header, in place of the baseline MSE-optimal bandwidth. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. Standard errors are omitted for space and available on request.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on not marrying before age 18, using Calonico et al. (2014), with the CER-optimal bandwidth (bwselect = cerrd) in place of the baseline MSE-optimal bandwidth. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. N is the total number of effective observations within the bandwidth. BW: Bandwidth (months). ^{u} Unstable estimate (still larger than half the standard deviation), reported but not interpreted.

Notes: *** p<0.001, ** p<0.01, * p<0.05, + p<0.1. Estimates are robust bias-corrected RDD coefficients (SE in parentheses) of CMB eligibility on not marrying before age 18, using Calonico et al. (2014), with a local quadratic polynomial (p = 2) in the running variable in place of the baseline local linear specification. Both specifications include country and survey-year fixed effects, the specification with controls additionally includes rural residence and religion and uses the women for whom both are observed. N is the total number of effective observations within the bandwidth. BW: Bandwidth (months).

Figure A5: Placebo Test: Fake Cutoffs

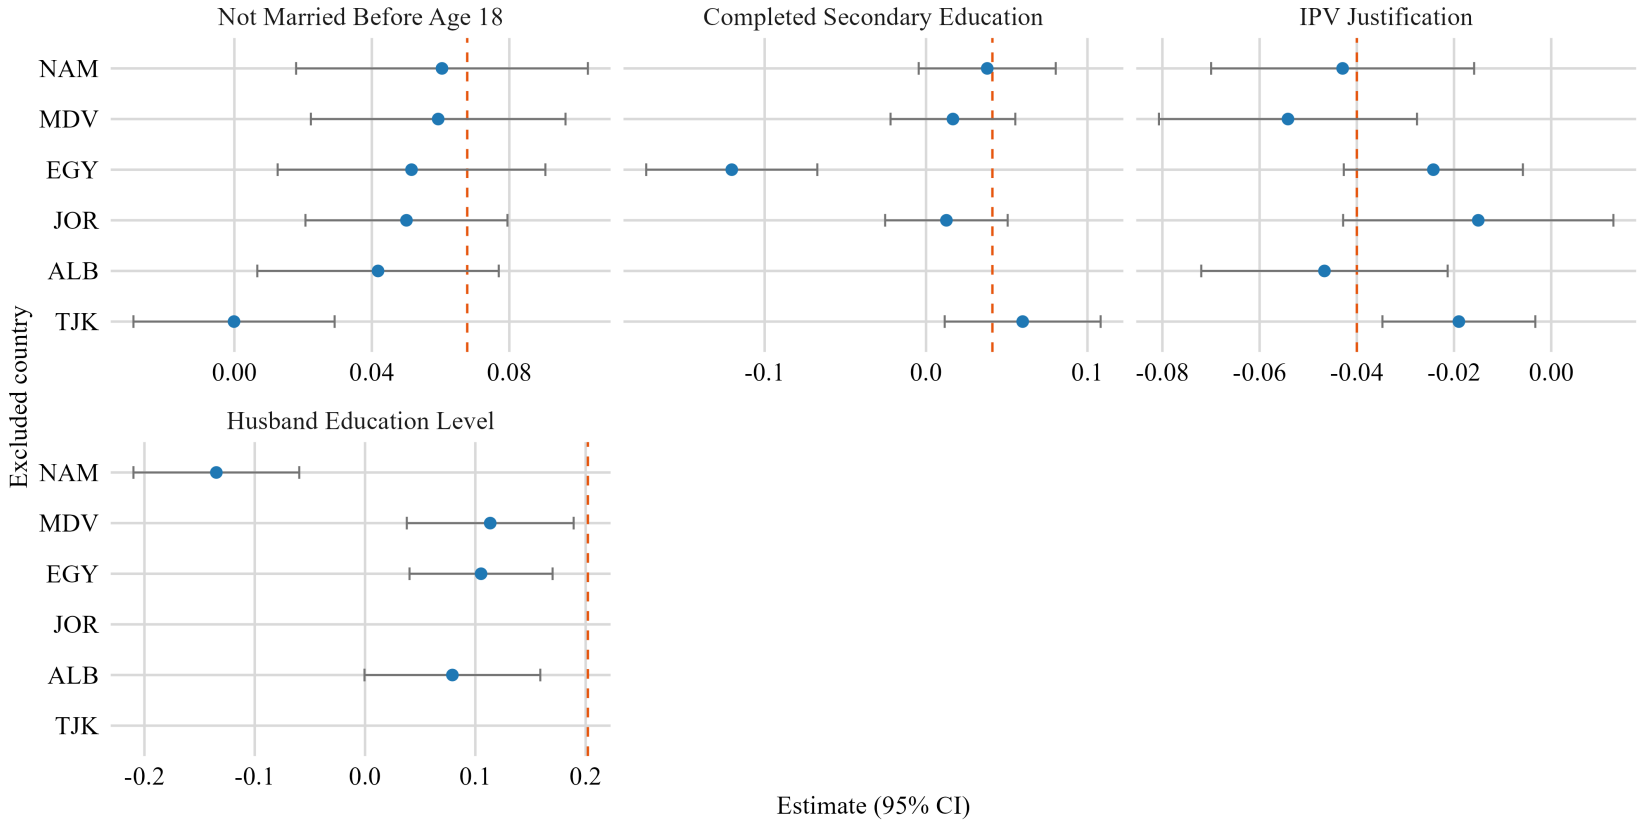

Notes: Each point is the robust bias-corrected first-stage RDD coefficient (Calonico et al., 2014) at a fake cutoff 24 or 12 months before or after the true CMB cutoff, estimated on one side of the true cutoff only so that the window never spans it. The orange point at 0 is the estimate at the true cutoff. Vertical bars are 95% confidence intervals. All regressions control for rural residence, religion, and country and survey-year fixed effects, and cluster standard errors at the primary sampling unit level. Solid lines and filled markers denote significance at the 5% level, dashed lines and hollow markers denote non-significance.

Figure A6: Leave-One-Country-Out: Full Sample

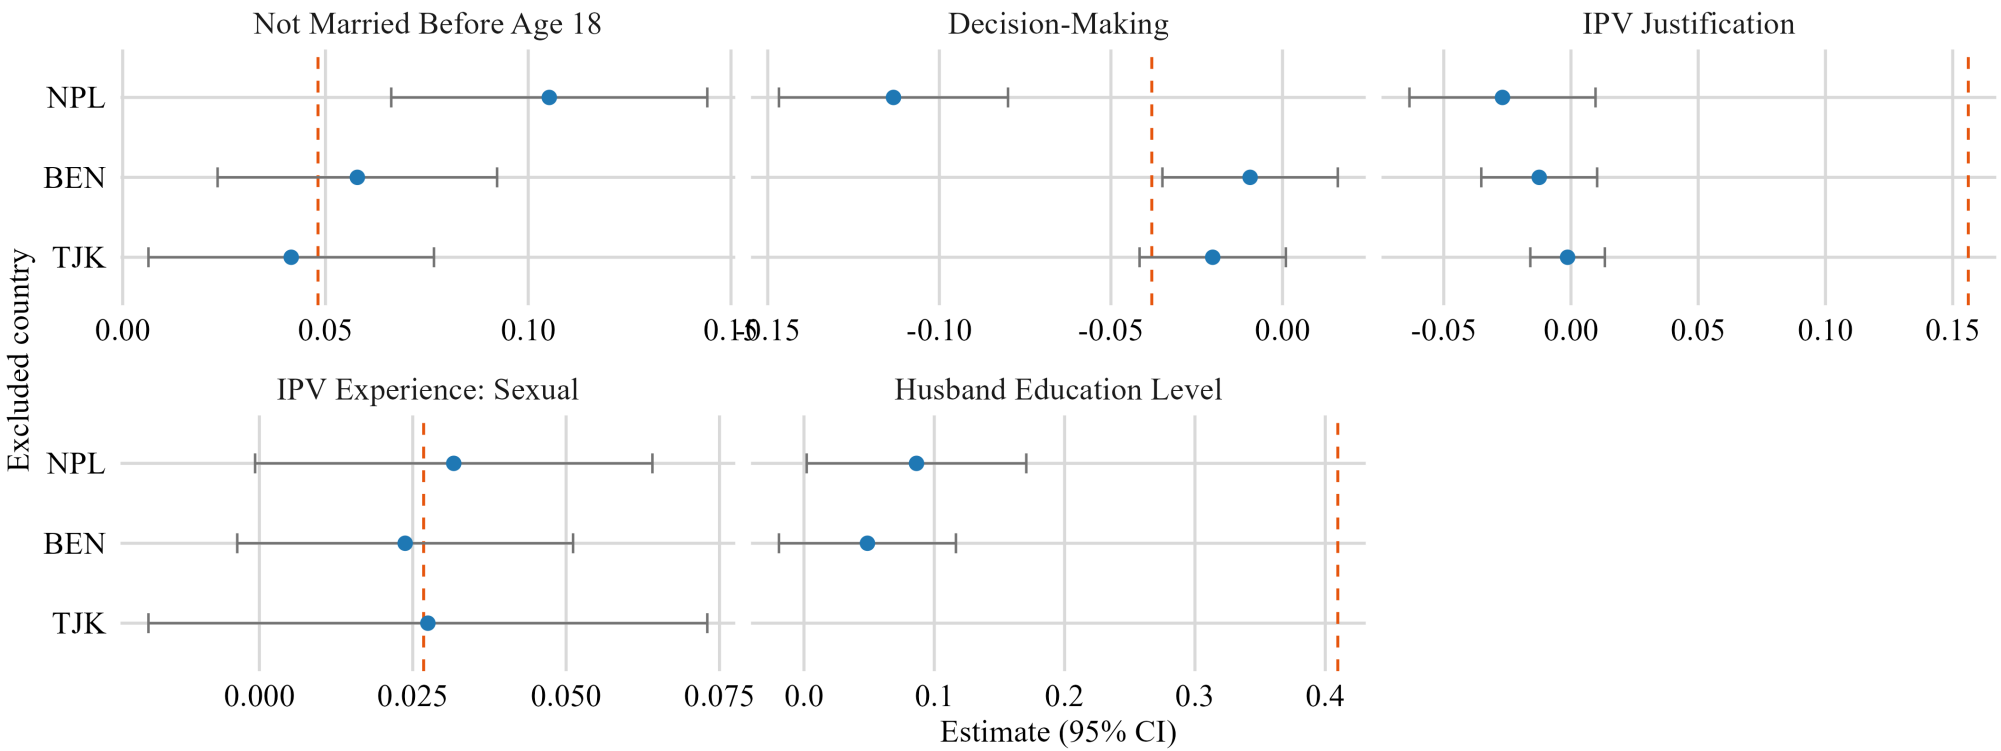

Notes: Each panel re-estimates the effect of CMB eligibility on the labelled outcome, dropping one country at a time from the estimation sample. Only outcomes with a significant effect ($p < 0.1$) in the subsample in the baseline estimation with controls are shown. Points are the point estimate excluding that country, horizontal bars are 95% confidence intervals. The dashed line is the baseline estimate using all countries.

Figure A7: Leave-One-Country-Out: Low Child Marriage Rate

Notes: Each panel re-estimates the effect of CMB eligibility on the labelled outcome, dropping one country at a time from the estimation sample. Only outcomes with a significant effect ($p < 0.1$) in the subsample in the baseline estimation with controls are shown. Points are the point estimate excluding that country, horizontal bars are 95% confidence intervals. The dashed line is the baseline estimate using all countries.

Figure A8: Leave-One-Country-Out: Strong First Stage Countries

Notes: Each panel re-estimates the effect of CMB eligibility on the labelled outcome, dropping one country at a time from the estimation sample. Only outcomes with a significant effect ($p < 0.1$) in the subsample in the baseline estimation with controls are shown. Points are the point estimate excluding that country, horizontal bars are 95% confidence intervals. The dashed line is the baseline estimate using all countries.
